The President of this Section, and *ex-officio* one of the Vice-Presidents of the Association, is Prof. Thomas Gray, of Terre Haute, Ind., the inventor of a great variety of ingenious apparatus, including the seismoscope and seismograph shown to the Association on their excursion to Terre Haute last year. His address was a carefully prepared discourse on problems in mathematical science. It was technical in character, and dealt with the teachings of mathematics and physics in their application to engineering.

Among the papers before this Section was one on Government timber tests, by B. E. Fermor, Chief of the Bureau of Forestry. He said there had been inaugurated in the forestry division of the Department of Agriculture a comprehensive series of tests and examinations of American timbers, the ultimate object of which is the solution of a biological problem—namely, to establish the relation of technical and physical qualities to each other and to conditions of growth. In the pursuit of this investigation, naturally, many questions of immediate practical value in the use of wood for engineering purposes will be solved. The novelty in this enterprise lies mainly in its comprehensiveness and scope. A very large number of tests alone on material of known origin and condition, and an exhaustive examination of the same will permit generalization and the recognition of laws of inter-relation. The work requires the organization of four distinct departments. First, the selection of test material from as many essentially different climatic and soil conditions as the species may occupy, five fully-matured and two young trees being carefully selected on each site and cut up for test material; secondly, the examination of the structure and physical condition of the test material, requiring the minutest detail; thirdly, the usual testing with special care; and, lastly, the compilation and comparative discussion of the results of the tests in connection with the physical examination and the known conditions of growth. Besides more trustworthy data than hitherto attainable of the qualities of our principal timbers, there is to be gained from this investigation a knowledge of conditions under which desirable qualities can be produced by the forest grower.

Prof. J. B. Johnson read a paper on the United States tests of strength of American woods, made at the Washington University Testing Laboratory, St. Louis.

SECTION E—*Geology and Geography*.

Prof. J. J. Stevenson, of New York, presided. His address was on the relations of the Chemung and Catskill on the eastern side of the Appalachian Basin. He traced the groups along the eastern outcrop from Tennessee into New York, across Southern and Western Pennsylvania, and eastward through Northern Pennsylvania again into New York, using the work of Prof. White and Messrs. Carill and Ashburne in Pennsylvania, and of Prof. Stevenson in Virginia and Pennsylvania, incidentally referring to the work of Profs. Hall and Williams in New York. In this way the continuity of the section was shown, and the insignificance of the variations was insisted upon strongly. An area in South-eastern New York and North-eastern Pennsylvania, in which the Chemung group is almost without trace of animal or vegetable life through the greater part of the thickness was described. The absence of life was thought to be due, not to fresh water, but to turbidity of the water in a shallow basin near the land. The facts that the horizons of fish-remains are much lower in the column than had been supposed, and that the plant-remains come in like manner from the home group, were thought to be of especial interest and importance. The conclusions to which the speaker was led were :—(1) That the series from the beginning of the Portage to the end of the Catskill form but one period, the Chemung, which should be divided into three epochs—the Portage, the Chemung, and the Catskill. (2) That the disappearance of animal and vegetable life on so great a part of this area toward the close of the period was due simply to gradual extension of conditions existing, perhaps, as early as the Hamilton period in South-eastern New York. (3) That the deposits were not made in a closed sea, but that the influx of great rivers with their load of *débris* made conditions in the shallow basin such that animal life could not exist. (4) That in the present state of our knowledge we are not justified in including the Chemung period in the Carboniferous age.

Notwithstanding the impending meetings of national and international Geological Societies, this Section was fully occupied with papers and discussion, mainly on the Glacial epoch, drift, &c. Mr. William Hallock read a paper entitled "A Preliminary Report of Observations at the Deep Well, Wheeling, W. Va." The question as to the conditions which exist in the interior of the earth, said Mr. Hallock, has always attracted much attention. The most important factor in the solution of this riddle is the determination or estimation of the temperatures there existing. The British Association has for years seized every opportunity to obtain data as to the rate at which the temperature increases as the earth crust is penetrated. The most recent and trustworthy contributions on this subject are by Mr. E. Dunker, of Halle, Germany, and were obtained from a 4170-foot well at Sperenberg, not far from Berlin, and a 5740-foot well at Schladabach, near Leipzig. These wells are both full of water, the circulation of which vitiates results or renders elaborate apparatus indispensable, and the thermometers must be protected from the pressure. The Wheeling deep well, sunk by the Wheeling Development Company, and by them generously dedicated to science, is 4500 feet deep, $4\frac{7}{8}$ inches diameter, and dry; cased only to 1570 feet. The strata there are nearly *in situ*, undistorted and dipping only 50 feet to the mile. More satisfactory geological conditions can scarcely be imagined. Being dry, ordinary United States Signal Service maximum thermometers were used, and no especial precaution needed to be taken to prevent circulation of the air. The thermometers were lowered and raised, and depths measured by a steel wire. Results :—

TABLE I.

Depth. Feet.	Temperature, Fahrenheit. Degrees.	Depth. Feet.	Temperature, Fahrenheit. Degrees.
1350	68·75	3125	88·40
1591	70·15	3232	89·75
1592	70·25	3375	92·10
1745	71·70	3482	93·60
1835	72·80	3625	96·10
2125	76·25	3730	97·55
2236	77·40	3875	100·05
2375	79·20	3980	101·75
2486	80·50	4125	104·10
2625	82·20	4200	105·55
2740	83·65	4375	108·40
2875	85·45	4462	110·15
2990	86·60		
		100	51·30

These observations, when plotted, show a slow increase for the upper half of the uncased portion, about 1° F. for 80 to 90 feet, whereas the lower part shows a more rapid increase—about 1° F. for 60 feet; the whole series giving a well-defined and regular curve, with a deflection at 2900 to 3000 feet, where an oil sand occurs. Practically all the rest of the uncased well is in shale. The increase in the rate at which the temperature rises as the bottom is approached can only be temporary, or we should have an inconceivable or improbable state of temperature at comparatively slight depths. The two distinct series of observations combined in Table I. nowhere disagree more than 0°·3 F., and hence are very trustworthy and accurate. Table II. gives a comparison of the results at the three great wells :—

TABLE II.

Name of well and location.	Feet for 1° F. Feet.	Total Depth. Feet.	Temperature at top. Degrees.	Temperature at bottom. Degrees.
Sperenberg, near Berlin	59·2	4170	47·8	118·6
Schladabach, near Leipzig	65·0	5740	51·9	135·5
Wheeling Development Company	—	4500	51·3	110·3
Top and greatest depths	74·3	4500	—	—
Mean of lower 3000 feet	75·4	4500	—	—
Mean of above two	74·9	4500	—	—

Inasmuch as the bottom of the well is some 3700 feet below sea-level, it seemed worth while to attempt barometer readings in it. The instruments used proved ill adapted to the work, and the results were unsatisfactory. Samples of air were taken at the bottom, but could not be analyzed in time for use. A series of observations in a coal mine near the well gave as a very probable value of the temperature of the top invariable stratum 51°·3 F. From the mean annual temperature of Marietta and Steubenville it might be taken at 52°·2 F. Drilling is temporarily stopped, but it is hoped that a depth of 5500 or 6000 feet may be reached. Mr. Anton Reyman, of the Development Company, has generously guaranteed half the expenses, and what is wanted is that some one shall furnish the other 3000 dollars, and enable the Wheeling well to be lifted from the second to the first place among the deep wells of the world.

SECTION F—*Biology*.

Prof. John M. Coulter, President of Indiana State University, gave the annual address, as President of Section F, on the future of systematic botany. He contended that for the systematists of to-day and of the future there must be three distinct lines of work, related to each other in natural sequence in the order presented, and each turning over its completed product to the next. (1) *The Collection and Description of Plants.*—He expressed great gratitude to the noble army of self-denying pioneer collectors, but claimed that the time had now come when the same amount of labour could be expended to better advantage, and that a race of field workers must be trained who shall follow their profession as distinctly and scientifically as the race of topographers. In reference to the work of description he read an unpublished note of Prof. Asa Gray, in which that distinguished botanist lamented the work of those who were incompetent. The speaker also expressed the opinion that the exclusive use of gross organs in the description of higher plants would be given up, and that the more stable minute characters would prove valuable aids in steadying diagnosis. A danger in the use of these minute characters was pointed out, viz. the tendency to use a single set of minute characters too far, and to make the fabric of a whole group conform to it. The character of a species is an extremely composite affair, and it must stand or fall by the sum total of its peculiarities, and not by a single one. There is nothing that involves a broader grasp of facts—the use of an inspiration rather than a rule—than the proper discrimination of species. (2) *The Study of Life-histories.*—The work of searching for the affinities of great groups is the crying need of systematic botany to-day. The speaker called attention to the danger of magnifying the importance of certain periods or organs in indicating affinities, and summed up what was said under this general head as follows :—"I have thus spoken of the study of life-histories to indicate that its chief function lies in the field of systematic botany; to suggest that it take into account development at every period and of every organ, and so obtain a mass of cumulative evidence for safe generalization; and to urge upon those not thoroughly equipped great caution in publication." (3) *The Construction of a Natural System*.–The speaker spoke of the necessity of constructing a natural system with easy advance in the knowledge of affinities, as a convenient summary of information, a sort of mile-post, to tell of progress and to direct future effort. The concluding summary was as follows :—" The points presented in this consideration of the third phase of systematic botany are that the last and highest expression of systematic work is the construction of a natural system, based upon the accumulations of those who collect and describe, and those who study life-histories ; that this work involves the completest command of literature and the highest powers of generalization ; that it is essential to progress for a natural system to be attempted with every advance in knowledge ; and that all the known facts of affinity, thus brought within reach, should be expressed in all systematic literature."

This Section, as usual, was the most crowded of all, forty-seven papers having been read before the Section itself, and many more before its two offshoots, the Botanical and the Entomological Club. This was another of the Sections which its Secretary considered to have had the most successful meeting on record. A feature now at every annual session is the report of members appointed the year before to study certain assigned questions. This year four such reports were presented :—Transpiration, or the loss of water in plants, was treated by Chas. E. Bessey and Albert F. Woods. " Movements of fluids in plants " was read by Prof. Wm. J. Beal, of Michigan. Dr. J. C. Arthur, of Purdue University, Lafayette, Ind., read a paper entitled " Gases in Plants." A paper was read by Prof. L. H. Pammel, of Ames, Iowa, on the absorption of fluids by plants.

SECTION H—*Anthropology*.

The youngest Vice-President at this session, if not the youngest man who ever held a Vice-Presidential office in the American Association, is Prof. Joseph Jastrow, whose age is 28 years. His address was entitled " The Natural History of Analogy."

Major J. W. Powell, Chief of the U.S. Geological Survey, exhibited and explained his linguistic map of North America, on which he showed the classification of languages of the aborigines.

Mr. Cushing read a paper on the Zuñi Indians, and danced the Messiah dance, which a few months ago was so much talked about, and almost involved a war with the Government.

SECTION I—*Economic Science and Statistics*..

Of all the Vice-Presidential addresses, that of Prof. Edmund J. James, of Philadelphia, before this Section, aroused the most widespread popular interest and attention, on account of the vital practical importance of the theme presented, which was " The American Farmer : his present economic condition and future prospects."

The silver question was carefully considered, and all who took part in the discussion agreed in opposing the free coinage schemes which are now so vehemently urged upon Congress.

The general business of the Association included a change in the constitution, so as to admit fifty foreign honorary members, and many recommendations to Congress as to forestry, water supply and management, and other topics. Preliminary arrangements were made to participate in the Columbian World's Fair in 1893. A Committee was appointed to solicit donations for the endowment of the Association with a fund of at least $100,000. Three hundred and seventy-one new members were elected, bringing the total membership up to about 2300, which is high-water mark in the history of the Association.

Prof. Joseph Le Conte, of California, was elected President ; and the Association adjourned, to meet at Rochester, N.Y., on the third Wednesday of August 1892.

RAIN-MAKING IN TEXAS.

THE announcement in the *Standard* about a fortnight since, that rain had been artificially produced in Texas by exploding oxyhydrogen balloons and dynamite, was probably received by most scientific men with a suspension of judgment. The somewhat sensational form of the report, the emphasis with which it dwelt on the unfavourable antecedent conditions, and the omission of all details that might enable us to form some rough estimate of the forces employed and of the resulting effects, seemed calculated to appeal to the barren emotions of astonishment and love of the marvellous rather than to the sober judgment of well-balanced minds ; and but for the fact that the experiments were stated to have been made by the officers of the U.S. Signal Service, which, on the hypothesis of a hoax, would have been a needless challenge to speedy denial, one might have been disposed to regard the story as only an additional instance of a kind of produce for which the Western States are somewhat notorious. The further accounts that have now reached us prove, however, that this is not one of Jonathan's amusing attempts to play off on the credulity of his simple-minded cousins across the Atlantic. Not only have experiments of the kind described been actually made, but they have been apparently successful, and they seem to have been repeated sufficiently often to render it at least improbable that this success has been entirely fortuitous. The improbable features of the *Standard's* report are, indeed, somewhat toned down ; the dryness of the local atmosphere was by no means so great as was to be inferred from the vague language of the *Standard's* informant ; but, as far as can be judged from the notices now before us, it seems unlikely that the rain which followed General Dyrenfurth's experiments would have occurred in the undisturbed course of natural events.

The experiments were made at a place known as Ranch C. One writer states that an intermittent series of experiments had been carried out for three weeks, and that " not in a single instance has rain failed to fall within ten or twelve hours after the explosion." But the number of trials is not stated—an omission the more to be regretted, because the improbability that the results are fortuitous increases in a certain geometric ratio of the number of successful repetitions. We have definite accounts of those made on August 18, 26, and apparently the morning of the 27th, and it is by no means clear that the evidence is not limited to these, although the expression quoted above would seem to imply otherwise. The first, that of August 18, was made about 3 p.m. There were at the time a few scattered clouds, but no indication of rain. The reading of the barometer is not reported, but the relative humidity of the air immediately before the experiments (presumably at the earth's surface) was not more than 60 per cent. of saturation. An oxyhydrogen balloon, the capacity of which is not stated, was exploded by electricity at an altitude of a mile and a quarter. Several kites, with packets of dynamite attached, were sent up immediately after the balloon, and the charges exploded by similar means, and " rendrock powder was distributed for a distance of two and three-quarter miles from head-quarters, and fired by igniting dynamos." These explosions " sent up great volumes of white smoke, which rose only a short distance, and was then beaten down by heavy rain, which at once began falling and continued for four hours and twenty minutes." Prof. Curtis, the meteorologist of the expedition, estimates that the rain covered an area of not less than 1000 miles.

On August 26 it is stated that " balloons containing several thousand feet of oxyhydrogen gas were sent up and exploded at heights varying from 1000 to 10,000 feet, and at sundown batteries on the ground began their work, and until 10.30 p.m. a constant cannonade was carried on under a sky of perfect clearness, lit by countless stars of a brilliancy seldom seen in the north. The barometer promised fair, and the hygrometer stood between dry and very dry," whatever these expressions may mean. The account continues :—" At 11 p.m. General Dyrenfurth withdrew his forces, and all retired for the night. Sleep, however, was soon interrupted, for at 3 a.m. the first return fire flashed from the heavens, when the rain-makers were roused by a crashing peal of thunder, and the rain was soon beating on the roof. At sunrise a magnificent double bow arched the heavens, and the downfall of rain did not cease till 8 o'clock a m. A number of heavy charges of dynamite were then made, and after every one the drops again poured down, till at last the clouds were entirely expended."

In these quotations is given all that is essential in the newspaper reports now before us. Although deficient in many details that it would be desirable to know, they are written by one who witnessed what he described, and there seems no reason whatever to doubt their genuineness and good faith; we may therefore, discuss the information they afford, without misgivings of its substantial trustworthiness.

It is not antecedently improbable that, in certain states of the atmosphere, the liberation of a large amount of heated gas consisting wholly or in great part of water vapour, at an elevation where aërial movements are but little retarded by terrestrial friction, may suffice to generate an ascending current; and elementary physical considerations teach us that a mass of air that would be called relatively dry at the lower level, will in ascending speedily become saturated and condense its surplus vapour, first as cloud, and eventually as rain, not indeed by acquiring more vapour, but in virtue of dynamic cooling as it progressively expands under the diminished pressure of greater altitudes. But unless the atmospheric strata thus immediately affected be already in a condition of unstable equilibrium, unless the vertical decrease of temperature in these strata is already somewhat greater than the adiabatic rate of decrement, so that the ascending movement once started can be maintained by the store of energy already present in the form of sensible temperature and the latent heat of the included vapour, the effect must of necessity be temporary and local—more of the nature of a small thunder-storm, or cloud-burst, than of the widely extended or sporadic rainfall that accompanies a barometric depression.

In fact, the possibility of rainfall production depends on the possibility of producing and maintaining an upward movement in the atmosphere. There is always some vapour present in the air, generally sufficient to form clouds when dynamically cooled by an ascent through two or three thousand feet; although such air, while resting on the ground and warmed by its contact, may be very dry as judged by our feelings and by the evidence of the hygrometer. The amount of energy yielded by any moderate provision of oxyhydrogen balloons and dynamite is but infinitesimal in comparison with that already locked up in the atmosphere and its vapour, and which, under the circumstances above specified, viz. a vertical decrease of temperature exceeding a certain fixed rate, is available for maintaining a movement once set up; and the part played by the heated gases of such experiments as those now described can be little more than that of a trigger that releases a detent.

It seems highly probable that on August 18 the atmosphere was in this unstable condition. Even in the warm stratum resting on the ground, the humidity was 60 per cent. of saturation, clouds (indicating saturation) existed at some height, and rain began to fall almost immediately on the conclusion of the explosions. It may be noticed, too, that the time of day was that at which the barometer is lowest and the humidity highest in the cloud-forming stratum, although, in fine weather, lowest at the ground surface. In the absence, then, of any observations of the temperature and humidity of the strata primarily stirred up by the exploding balloons and dynamite, it seems likely that they were in a condition to maintain ascending currents once started, and even to communicate the disturbance to regions around.

On the 26th, the atmosphere was evidently in a much more inert condition, and four hours elapsed before rain fell, the disturbance being then apparently more local, and of the nature of a thunder-storm. However, with the meagre data as yet before us, it would be premature to attempt any critical discussion of the processes in operation.

It is needless to say that popular theorizing, on this as on most other physical phenomena, concerns itself chiefly with the things that are most obvious to the senses, but often have little or nothing to do with the process. Thus we find that attention has been fixed on the explosion; and we are told that the idea of breaking clouds by producing a motion in the air, and so destroying the equilibrium of the suspended globules of moisture, which in coalescence form rain, is not a new one; that it was the custom to keep a cannon in French villages, with which to fire at passing clouds and thus hasten the downpour; that at the battles of Dresden and Waterloo the concussion of the air by the cannonade led to the descent of torrential showers; and we are reminded that "in the same way" rain follows a peal of thunder caused by the passage of a lightning-flash through a moisture-laden atmosphere, &c. Now, all this noise and disturbance have no more to do with the production of rainfall than has the thrashing which the village rain-maker of Central India receives from his fellow villagers to stimulate him to fresh exertions when he is thought to have neglected the performance of his official duties, or the London street-boy's whistle, with which Sir Samuel Baker startled a rain-making king in the Southern Soudan, and which was followed by such a deluge that even the rain-making potentate implored him to arrest the working of the spell.[1] The effect of a concussion, as such, is to produce an instantaneous compression of the air, and a momentary heating in a wave which travels away at the rate of about 1000 feet per second, and is incapable of generating any translational movement of the atmosphere, and certainly of promoting condensation. Nor do we know of any recorded observations in support of the idea that it can cause the coalescence of cloud corpuscles into raindrops. Neither does the concussion of the air by a thunder-clap stand to the downpour that follows it in the physical relation of cause to effect. In this case Sir John Herschel adopts the opinion originally put forward by Eeles, that the order of succession is the reverse of that here assumed, that the formation of the rain-drop is the antecedent phenomenon, and the lightning-flash (and *ergo* the thunder) the consequent; the electrical discharge being determined by the sudden concentration of the electricity of (say) one thousand corpuscles on the surface of the single resulting rain-drop, in which case its intensity would be increased ten-fold. What causes the coalescence is still a matter of much obscurity, though some light has been thrown upon it by the ingenious experiment exhibited by Mr. Shelford Bidwell at the Royal Society's *conversazione* on May 14, 1890, and described in vol. xlii. (p. 91) of this journal. When the shadow of a small (condensing) steam jet was thrown upon a white screen, under ordinary conditions, it was of feeble intensity and of a neutral tint; but when the jet was electrified, the density of the shadow was at once greatly increased, and it assumed a peculiar orange-brown tint. It appeared that electrification promoted the coalescence of the exceedingly minute particles of water contained in the jet, thus forming drops large enough to obstruct the more refrangible rays of light. On this view, then, electrification would appear to be the cause of coalescence, and the electrical discharge the ulterior result; but as yet we know too little of the molecular processes concerned in the formation of a raindrop to attempt anything like a complete theory.

---

[1] This story has probably been told by Sir Samuel in one of his well-known works on Africa, and is too good to be spoilt by condensation. It is, at all events, authentic, the present writer having heard it from his own lips at a Simla dinner-table.

In conclusion, while we cannot but recognize the high interest of General Dyrenfurth's results, with the imperfect information at present before us we cannot regard them as conclusive. It is the characteristic weakness of all experiments of the kind that many of the essential circumstances are scarcely ever recorded, or perhaps even capable of being brought within the limits of observation: and thus the logical conditions of a proved conclusion cannot be fulfilled. For instance, it is very unlikely that anything is known of the state of the atmosphere in respect of its humidity and its vertical temperature decrement at the elevation at which the balloons were exploded, and yet, as we have seen, these data lie at the very root of the whole matter. However, arrangements are being made for further operations at El Paso and in Western Kansas, so that it will not be long before the highly interesting and practically important problem of stimulating the precipitation of rain will receive a more satisfactory solution.

H. F. B.

NOTES.

THE Permanent Committee of the International Committee of Weights and Measures is now holding its meeting at Sèvres, near Paris. The Committee includes: Dr. Foerster (Germany); M. J. Bertrand (France); Dr. Benoît, Director of the Bureau at Sèvres; Mr. H. J. Chaney (Great Britain); Prof. Govi (Italy); Prof. Krusper (Hungary); Prof. Lang (Austria); Mr. H. de Macedo (Portugal); M. Stas (Belgium); Prof. Thalen (Sweden); Dr. Wild (Russia). The Committee has recently lost its President (General Ibañez); and one of the objects of the present meeting is to elect a new President; an election which will doubtless fall on the senior member of the Committee, Dr. Foerster.

THE members of the Heilprin Expedition, who have lately returned from the west coast of Greenland, give an extremely unfavourable account of the position in which they were obliged to leave Lieutenant Peary. His leg was broken in Melville Bay on July 11. Dr. Hughes, who has recorded in the Philadelphia *Press* the adventures of the Expedition, describes how the accident happened. "While we were going astern for the last time," he says, "to make the butt that forced us through a barrier of ice into comparatively clear water, Lieutenant Peary stepped behind the wheel-house to see how things were going. With a crash the rudder struck a piece of ice, and the next instant his leg was crushed between the rudder gearing and the side of the wheel-house. He was carried below into the cabin, when an examination showed that his right leg was broken square across just above the knee. Everything possible was done for him." When he had recovered from the shock, and had thought the matter over, he decided to go on to Whale Sound, trusting that by next spring his leg would be so far mended that he would be able to accomplish the object of his expedition. His friends thought it would be better for him to return, but they could not help admiring his spirit, and resolved to do everything in their power to further his aim. The shores of Whale Sound proved to be completely blocked with ice, so the *Kite* steamed north to McCormick Bay, on the northern shore of Murchison Sound, which they reached on July 25. Here a space of about two miles was comparatively clear; and Lieutenant Peary's men went ashore, and reported that the place was well suited for their head-quarters. A site was selected on the south shore of McCormick Bay, in latitude 77° 43′, and a wooden house erected, which Lieutenant Peary declared to be "substantial and warm enough." On July 30 the Heilprin party had to leave him, which they did with sad forebodings. Mrs. Peary bravely insisted on remaining with her husband, and they have six companions. The Lieutenant hopes to start in the spring for the unexplored interior of Greenland, but Dr. Hughes says: "It is the deliberate opinion of all our party—and this opinion is indorsed fully by all the officers of the *Kite*—that unless a relief expedition be sent to Lieutenant Peary next summer, he and his party will never be seen again alive." It is doubtful whether the food supply is sufficient; and it is thought most improbable that whalers will take them away next summer. In that case their only resource would be the whale boats, in which they would have to traverse 500 miles of ocean "filled with floes and bergs, and often shrouded with fog or swept by terrible storms."

AN earthquake of great violence caused immense damage in the Republic of San Salvador on September 9. According to reports sent from the capital of the country to the *New York Herald*, there had been indications for several days that a seismic disturbance of more than usual power might be expected. The volcanoes of San Salvador, San Miguel, and Izalco had been unusually active, and deep subterranean rumblings with slight earth tremors had been felt. At 1.55 a.m., on September 9, the earthquake began in the city of San Salvador with a slight tremor, which gradually augmented. The duration of the first shock was ten seconds, during which time a frightful subterranean noise was audible in every part of the city. While the shock lasted, the earth rose and fell in long waves, and even strong men were unable to keep their feet. The walls of houses cracked, and then tottered and fell. In the capital alone 40 persons were killed, and 50 or 60 seriously injured. The experience of towns in the country seems to have been still worse. Of 320 houses at Comasagua only eight remain standing, and the loss of life there was great. Analquito has also been almost completely destroyed, and Cojutepeque, Santa Tecla, San Pedro, and Masahuet were so badly shaken as to be practically ruined. It is feared that the earthquake has been even more disastrous than those of 1854 and 1873.

IN the Isle of Fayal, among the Azores, several shocks of earthquake were felt on August 27 and 28.

MR. TUCKWELL writes to us from Loughrigg, Ambleside, that an aurora was seen there on Friday night, September 11. The arch spanned the heavens from south-west to north-east, passing nearly through the zenith. It was white, with slight coruscations at its south-west base. It was first seen at 9 p.m.: it had faded by 10 o'clock.

A NEW department of physics and electrical engineering will be begun this session at the new branch of the Manchester Technical School in Whitworth Street, where a large well-lighted warehouse is being fitted up for the purpose. The building will be lighted by electricity, the installation being fitted up with especial regard to instruction. For the latter purpose, the electric light installation in the Central School in Princess Street will also be available.

THE Library Association is holding its annual meeting this week at Nottingham. Mr. Robert Harrison, of the London Library, presides. The meeting began yesterday in the large theatre of the Nottingham University College.

THE Industrial Society of Mulhouse has issued a programme of prizes which it proposes to give for work done in the year 1891–92. A copy will be sent to anyone who applies for it to the Secretary of the Society. The prizes are very numerous, and are to be granted for work of many different kinds in connection with the application of scientific methods to industry.

A Conference on Conifers will be held at Chiswick, in connection with the Royal Horticultural Society, in October. It is hoped that this Conference will not only draw attention to the best of these trees and shrubs from a garden or landscape point of view, but show what are the best varieties to plant for English-grown timber, as well as the different uses and suitabilities of the various foreign-grown timbers. The co-operation of landowners and others who may have planted these trees or shrubs in years past, or who take a present interest in them, is specially invited.

Dredgers working in the Tiber to prepare for the construction of a new embankment brought up on September 12 a magnificent ancient Roman bronze helmet. It is perfectly preserved, and is decorated with bas-reliefs. Signor Rossi, the Italian archæologist, assigns it to the second century before the Christian era.

According to the Calcutta correspondent of the *Times*, it is understood that the Ameer of Cabul is taking steps to obtain from England a geologist, a chemist, two miners, and a number of mechanics.

The Royal Meteorological Institute of the Netherlands has just issued another useful work in maritime meteorology, viz. "Routes for Steamships between Aden and the Straits of Sunda." A previous edition appeared in 1881, but since that time steam navigation to the Dutch Indies has greatly increased, and consequently the number of logs received has afforded sufficient materials to allow of a fuller discussion of the outward and homeward routes for each month. Although there is a certain amount of regularity both as regards the monsoons and currents, yet there are considerable differences both in force and direction in the same months of different years, which cannot be taken into account in laying down general routes; but tracks laid down with great care from the most complete data available will give the best chance of successful passages. We cannot enter here into the details of the results, but we may mention that the tables and charts contained in the work show for each 10° of longitude the number of vessels which have cut those meridians in different latitudes, and the means of the number of hours taken. The tracks show that a very considerable divergence from the most direct routes is recommended in certain months, according as the east or west monsoon may be blowing. The usefulness of the work is attested by the fact that copies have been ordered for their vessels by the French, Russian, and Italian Governments.

It is expected that in no other department of the "World's Columbian Exposition" will there be a greater diversity of exhibits than in that of mines and mining. Not only will there be a magnificent array of diamonds, opals, emeralds, and other gems, and of the precious metals, but a most extensive collection of iron, copper, lead, and other ores, and of their products; of coal, granite, marble, sandstone, and other building stone; of soils, salt, and petroleum. A sub-department will take special charge of the coal and iron exhibit, and later of that of copper and lead.

Mr. O. Chanute, a well-known engineer of Chicago, has been studying the methods of preparing wood chemically to resist decay, and has expressed the opinion that great economies might be realized in America by the general adoption of these methods on railways. *Science* says he recently examined some experimental railroad ties of the most perishable kinds of wood prepared by what is known as the zinc-tannin (Wellhouse) process, in St. Louis, in 1881 and 1882, and laid in the tracks of the Atchison, Topeka, and Santa Fe Railroad, at Topeka, Kan., and La Junta, Col. After nine or ten years' exposure they show excellent results, whereas they would have lasted but from one to four years if unprepared. Unprepared ties of the same kind of timber, laid at the same time, adjoining to the prepared ties, have all decayed and been taken up, while present appearances indicate that the prepared ties (red oak, black oak, and Colorado pine) are likely to show an average life of ten to fifteen years or more. Mr. Chanute calls attention to the fact that the zinc-tannin process not only preserves ties against decay, but hardens them as well. It is found on one railroad that after three years' exposure treated hemlock ties hold the spike as well, and cut less under the rail than untreated white oak.

Some time ago the Field Naturalists' Club of Victoria organized an excursion to the Kent group of islands, the object being to collect specimens, and to determine whether the group is most nearly related with Victoria, to which it is closest geographically, or with Tasmania. At the annual *conversazione* of the Club, held recently, Mr. C. A. Topp, the retiring President, referred to the results of the expedition. The bulk of the fauna and flora was found to be common to Victoria and Tasmania, but there were six or seven varieties of birds peculiar to Tasmania to two peculiar to Victoria. The conclusion was that the islands had been separated from Tasmania after that island was disjoined from the mainland. Among the plants, several forms were found varying somewhat from the typical forms of the same species on the mainland; while it was interesting to find that the arboreal short-eared opossum had changed his habits so far as not to feed on the leaves of the eucalypt, and to keep to the ground.

In a paper in the American *Engineering Magazine*, on ventilation, Mr. Laurence Allen contends that in very many schools the quantity of pure air admitted is not sufficient to expel the foul air. To maintain the air in a good sanitary condition in a properly constructed schoolroom, his experience confirms the amount required as stated by Billings, to wit, 60 cubic feet of air for each occupant per minute. For 100 pupils this amounts to 360,000 cubic feet per hour. How many schools come up to this requirement? In the United States, says Mr. Allen, there are many schools that contain 100 pupils and do not introduce more than 25,000 feet of pure air per hour, and even that is rendered in a measure ineffective, because the air is not properly admitted. "The pupils do not die in the poisoned atmosphere; many of them will appear reasonably healthy. So do many persons who visit and tarry in malarial districts. But though the effects are not immediate and striking, they are sure, permanent, and easy to be traced to their causes in after years, by those who make a study of disease and its causes. It is scarcely less humane to kill a child than, by wilfully ignoring sanitary requirements, to cripple it for life, physically, mentally, and morally, as children are being crippled to-day in the vile atmosphere of many schools."

In a paper published in the current number of the Journal of the Anthropological Society, Mr. J. J. Lister refers to the great development of the arms and chests of the natives of Fakaofu (Bowditch Island, Union Group). He thinks it may be due to the fact that they are obliged to go about so much in canoes. Sir Joseph Lister, who took part in the discussion which followed the reading of this paper, remarked that he would not have expected the frequently repeated action of paddling to produce lengthening of the arms, although he could understand its resulting in increased size of chest. He pointed out that the natives of Tonga were also accustomed to use canoes, and hence it was not clear that the phenomenon could be traced to the cause assigned. Mr. Lister replied that, although the Tongans use canoes, canoe work is not so essential a part of their lives as it is in the case of the natives of Fakaofu. The natives of the island of Tongatabu have many avocations quite apart from the sea, for they live on an island twenty-two miles long, and many villages are situated some distance from the water. The natives of Fakaofu, on the other hand, live crowded together on a small islet situated on a ring of reefs, and to meet almost every need of their lives they must do more or less paddling.

MR. IVAN PETROFF, the United States special census agent, has been engaged in taking the census of the natives of Nunivak Island, in Behring Sea, in 60° N. lat. He found the population to consist of over 600 natives. It was previously supposed that over 300 people occupied the island. There are no white men there, and the natives live in a most primitive style. Their only food is the flesh of the walrus, and their only wealth consists of ivory obtained from the tusks of that animal. There are few land otter, but, apart from these, the natives catch no fur-bearing animals.

DR. L. WEBSTER FOX is of opinion that savage races possess the perception of colour to a greater degree than do civilized races. In a lecture lately delivered before the Franklin Institute, Philadelphia, he stated that he had just concluded an examination of 250 Indian children, of whom 100 were boys. Had he selected 100 white boys from various parts of the United States, he would have found at least five of them colour-blind: among the Indian boys he did not discover a single case of colour-blindness. Some years ago he examined 250 Indian boys, and found two colour-blind, a very low percentage when compared with the whites. Among the Indian girls he did not find any. Considering that only two females in every 1000 among whites are colour-blind, he does not think it surprising that he did not find any examples among the Indian girls.

DR. J. FRANK lately reported to the Chicago Medical Society the case of a man who periodically sheds his skin. The shedding began in his first year, and has since then occurred regularly every July. He is taken with feverish tremors, increasing almost to paroxysms. He undresses, lies down, and within a few minutes the skin of the chest begins to turn red. The redness rapidly extends over the entire skin, and the feverish tremors continue uninterrupted for about twelve hours. Then he rises, dresses, and walks about in perfect health. The skin now begins to peel, and ten hours later it comes off in great patches. From the arms and legs it can be peeled off exactly like gloves or stockings. As the old skin comes away, a new epidermis, as soft and pink as a baby's, is revealed. This new skin is very sensitive; the patient has to wear softened gloves and moccasins for about a week. After the old cuticle has been entirely removed, the finger and toe nails begin to drop off—new nails literally crowding them out. Finally, the change is complete, the man has a new skin and a new outfit of nails, and is ready to return to the mines. A lady in Washington County, Nebraska, who is thirty-nine years old, has written to Dr. Frank that since 1876 she has had a like experience every second or third year.

THE Orcutt Seed and Plant Company, San Diego, California, have issued an interesting descriptive list of Californian trees and flowers. The writer thinks that there is perhaps no country in the world where the early spring flowers so change the face of the earth from a desolate waste to a beautiful garden as on the Pacific coast—hills, mesas, mountains and valleys, and the arid plains of the desert, alike quickly responding to the vivifying rain. "California," he says, "has probably already furnished to the horticulturist a greater variety of beautiful flowers and stately trees than any other State in the Union. Yet many others are awaiting the appreciation of man, or wasting their sweetness on the desert air."

A PAPER on malformations of the bill in birds, by Mr. W. P. Pycraft, has been reprinted from the Transactions of the Leicester Literary and Philosophical Society. The most common kinds of malformation are those resulting from overgrowth of the horny sheath, and those arising from injury. Mr. Pycraft discusses these first, and then considers malformation due to embryonic disturbance.

"SYMONS'S British Rainfall, 1890," which has lately been published, contains, we need scarcely say, an enormous mass of information as to the distribution of rain over the British Isles during the year to which the volume relates. Mr. Symons points out that the only important alteration in this issue is that due to the completion of the decade 1880–89, which has enabled him to use the average for that period as a basis of comparison. He also calls attention to an article on the evaporation from soil, and to the details given as to the great rain of July 17.

THE operatives' lecture delivered at the Cardiff meeting of the British Association by Prof. Silvanus P. Thompson has been published by Messrs. E. and F. N. Spon. The subject is "Electricity in Mining."

"THE Hand-book of Jamaica for 1891–92" has just been issued. This is the eleventh year of publication. Mr. S. P. Musson and Mr. T. Laurence Roxburgh have done their best to present the fullest and latest information obtainable; and everyone who has occasion to consult the book will appreciate the care and thoroughness with which their task has been fulfilled.

A NEW edition, revised and enlarged, of the "Alkali Makers' Pocket-book," by Prof. Dr. Lunge and Dr. Hurter, will be issued in a few days in Messrs. Whittaker's Specialists' Series. As the size of the page has been somewhat increased, the designation "Hand-book" has been substituted for "Pocket-book." The same publishers are about to issue "A Practical Hand-book on the Telephone," dealing specially with telephonic exchanges, by Mr. Joseph Poole.

MESSRS. RAITHBY, LAWRENCE, AND CO. have issued a second edition, revised and enlarged, of "Simple Recipes for Sick-room Cookery," by Mrs. Buck. The writer produces an excellent impression at once by the sensible tone of the preface, in which she gives some general counsels as to the proper way of dealing with the food of the sick.

THE new number of the Journal of the Royal Horticultural Society contains, besides extracts of proceedings, a number of interesting papers. Mr. W. Warren writes on Persian cyclamen; the Rev. W. Wilks on hardy cyclamen; Dr. M. T. Masters, F.R.S., on germination of cyclamen. Snowdrops form the subject of papers by Mr. J. Allen, Mr. D. Melville, and Mr. F. W. Burbidge. There are also papers on the cultivation of hardy bulbs and plants, by Herr Max Leichtlin; Lachenalias, by Mr. F. W. Moore; Cape bulbs, by Mr. J. O'Brien; and hybrid Rhododendrons, by Prof. Henslow.

THE volume containing the Proceedings and Transactions of the Royal Society of Canada for 1890 includes papers on the American bison, by Charles Mair; the Vinland of the Northmen, by Sir Daniel Wilson; unit measure of time, by Sandford Fleming; a peculiar form of metallic iron found in Huronian quartzite on the north shore of St. Joseph Island, Lake Huron, Ontario, by G. C. Hoffmann; sun-spots observed at McGill Observatory, by C. H. McLeod; a test of Ewing and MacGregor's method of measuring the electric resistance of electrolytes, by J. G. McGregor; the later physiographical geology of the Rocky Mountain region in Canada, by G. M. Dawson; fossil plants from the Similkameen Valley and other places in the southern interior of British Columbia, by Sir J. W. Dawson.

MESSRS. SWAN SONNENSCHEIN AND CO. will issue the following books during the autumn season:—"The Colours of Animals," by Prof. Beddard, with coloured and other plates and woodcuts; "Text-book of Embryology: Man and Mammals," by Dr. Oscar Hertwig, Professor of Comparative Anatomy in the University of Berlin, translated and edited from the third German edition (with the assistance of the author) by Dr. E. L. Mark, Professor of Anatomy in Harvard University, with 389 illustrations and 2 coloured plates; "Text-book of Embryology: Invertebrates," by Drs. Korschelt and Heider, of the University of Berlin, translated and edited by Dr. E. L. Mark, with several hundred illustrations; "Text-book of Animal Palæontology," by Dr. Thomas Roberts, designed as a supplement to Claus and Sedgwick's "Text book of Zoology," illustrated; "Text-book of Geology," adapted from the work of Dr. Emanuel Kayser, Professor in the University of Marburg, by Philip Lake, of St. John's College, Cambridge, with illustrations; "Text-book of Zoology," by Dr. C. Claus, of the University of Vienna, and Adam Sedgwick, F.R.S., Vol. II. "Mollusca to Man," third edition; "The Geographical Distribution of Disease in England and Wales," by Alfred Haviland, M.D., with several coloured maps; "Introductory Science Text-books"—Additions: Introductions to the study of "Physiography," by H. M. Hutchinson; "Zoology," by B. Lindsay; "Amphioxus," by Dr. B. Hatschek, of the University of Vienna, and James Tuckey; "Geology," by Dr. Edward Aveling; "Physiological Psychology," by Dr. Th. Ziehen, of the University of Jena, adapted by Dr. Otto Beyer, with 21 figures. "Young Collector Series"—Additions: "The Telescope," by J. W. Williams; "British Birds," by the Rev. H. C. Macpherson; "Flowering Plants," by James Britten; "Grasses," by W. Hutchinson; "Fishes," by the Rev. H. C. Macpherson; "Mammalia," by the Rev. H. C. Macpherson.

AN instrument for optical comparison of transparent liquids, named a *liquoscope*, has been recently devised by M. Sondén, of Stockholm. Two hollow prisms holding the liquids are separated by a partition at right angles to the refracting angle. The whole is placed in a vessel filled with glycerine, and which allows of vision in a horizontal direction through plane glass plates. The deflection of the light rays through the prisms is thus compensated. So long as the two liquids have the same optical action, one sees a distant mark (say a black paper strip on a window) as a straight connected line; but its halves are relatively displaced if the liquids have different refractive power. The amount of displacement gives a measure of the difference, the positive or negative nature of which also appears from the direction of displacement. The author recommends his apparatus for chemical purposes, especially comparison and testing of fats and oils, analysis of glycerine, &c., and detection of margarine in butter, margarine greatly lowering the index of refraction.

HERR HUFNER has lately pointed out some of the biological bearings of the fact (observed in experiment along with Herr Albrecht) that long light-waves are much more strongly absorbed by water than short ones. If the lower marine animals had, like man, the liveliest light perception with yellow rays, and a certain intensity of light were necessary to them, they must live at a less depth than if their visual organs were most strongly affected by short-waved rays. Thus, *e.g.*, if they needed as much yellow light as that of the full moon, they could not live deeper than 177 metres (say, 590 feet). Yet they are found at all depths where food, oxygen, and a suitable temperature exist. On the other hand, the existence of plants having chlorophyll depends on light, and we might expect that the distribution of non-parasitic plants would be very limited; which is the case, no plant-organisms being found under 200 fathoms. Green plants assimilate best in yellow light; and supposing plants to assimilate in moonlight they would find their limit at the above depth (177 metres). But while yellow is here weakened to 0·0000016 of its brightness, indigo blue has still 0·007829 of its original strength, and the assimilation with blue rays will be 660 times as strong as with yellow. Different coloured marine plants react differently according to the colour of light, and they have accordingly different distribution in depth.

THE additions to the Zoological Society's Gardens during the past week include two Pinche Monkeys (*Midas œdipus* ♂ ♀) from Granada, presented by Mr. A. Aitken; a Fallow Deer (*Dama vulgaris* ♂), British, presented by Mr. J. Johnston; a Persian Gazelle (*Gazella subgutturosa* ♀) from Persia, presented by Baron Ferdinand de Rothschild; a Common Cormorant (*Phalacrocorax carbo*), British, two Yellow-browed Buntings (*Emberiza chrysophrys*), two Red-backed Buntings (*Emberiza rutila*), a —— Bunting (*Emberiza cioides*), two Japanese Greenfinches (*Fringilla kawarahibi*, var.) from Japan, purchased; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE LINEAR ARRANGEMENT OF STARS.—Although the arrangement of stars in curves has often been noted and studied, little attention has been paid to what is apparently a more striking and prevalent feature, viz. straight lines and parallel arrangement of pairs, lines, and bands of stars, and of irresolvable wisps. Our knowledge of the structure of the sidereal universe is therefore extended in the required direction by some results obtained by Mr. T. W. Backhouse from observations which he has made during the last nine years in Sunderland. The area of the sky selected for scrutiny is that portion of the Milky Way included between 15, 13, 8 Monocerotis, α Orionis, ζ Tauri, and 5, μ, ξ Geminorum; and the configurations in this portion have been examined chiefly with a binocular field-glass of 2·05 inches aperture. The observations have been divided into sections, referring respectively to lines and parallel arrangements of stars, to those in clusters, to nebulous wisps, to nebulæ, and to miscellaneous lines. In these are given the detailed structure in different parts of the area showing various systems of parallel lines and wisps, together with their position-angles referred to that portion of Gould's galactic equator which runs through the middle of the area in question. The parallel arrangement of the stars, and an arrangement in straight lines, is strikingly obvious from the maps which illustrate the tabulated results of the observations. Besides the maps, sixteen figures have been drawn to show the various angles of position of the lines and streams with reference to the central line or axis of the Milky Way. From these figures it is apparent that the angles of position are grouped more numerously in certain directions than in others, the principal directions being nearly parallel to the galactic equator. Also, there is a great deficiency of position-angles at right angles to this equator. A wonderful case of radiation of stars and wisps in a fan-shaped group has been found, 68 Orionis being approximately the centre. One conclusion derived from the investigation is, that the stars and wisps in parallel lines are probably in the same region of space; and therefore that the majority of the stars in extensive tracts of the area examined are really near one another.

WOLF'S PERIODIC COMET.—This object can now be fairly seen by means of a small telescope. It will pass through the Hyades about September 25, and be 3° south of Aldebaran on October 2. The following ephemeris, from one given by Herr

Thraen in *Astronomische Nachrichten*, No. 3054, shows that the comet crosses the equator near the end of October :—

Ephemeris for Berlin Midnight.

It will be seen that the comet is now nine times brighter than at the date of discovery (May 4). The maximum brightness will be reached about October 19.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE Address of the President of the Geological Section having been devoted to the general questions involved in the origin, association, and working of coal, it was natural that other papers on the economic side of the science should claim considerable interest. Prof. Boyd Dawkins stated that the Channel Tunnel boring had been carried to a depth of 1500 feet, with the result of penetrating coal-measures dipping gently to the south at 1113 feet. Six seams, containing 10 feet of workable coal, had been pierced between that depth and the present bottom of the boring. The author endeavoured to show the probability that a thick series of coal-measures, with workable coals like those of Liége on one side and Somerset on the other, would be met with if the boring were continued, and pointed out the advantage possessed by the south-eastern coal-field in its moderate depth and the comparatively uncrushed character of the coal.

In an exhaustive paper Mr. Topley summarized the chief facts bearing on the origin of petroleum. He pointed out that, while the American oil was mainly derived from Palæozoic rocks, that in Europe and Asia came largely from Secondary beds, and the large Caucasian supply was drawn from rocks of Miocene age. The essential conditions for the supply of oil appeared to be, a porous rock, generally of sandstone or limestone, which served as a reservoir and was underlain by or contained beds largely consisting of organic remains, with an impervious cover of shale. In many cases the limestone had been dolomitized and transformed into a cavernous rock which was capable of storing the gas and oil. Such rocks can contain from one-eighth to one-tenth of their bulk of oil. The oil was driven to the surface by artesian pressure, and so gas was generally met with on the summits of anticlines and oil on their flanks. Where the rocks were very highly disturbed oil occurred, but not in very great abundance, while gas was rarely found.

Mr. Ross, in a paper on the same subject, endeavoured to prove that the oil was mainly generated by the action of solfataric volcanic energy upon beds of limestone, basing his conclusion on the occurrence of hydrocarbon and sulphurous vapours in solfataras, and the constant association of rock salt, dolomite, and gypsum with the rocks yielding petroleum. He exhibited equations to show that the action of sulphur dioxide and sulphuretted hydrogen on carbonate of lime, with or without water and peroxide of hydrogen, was capable of producing the ethylene and marsh gas derivatives, and he quoted experiments of Bischof to show that sulphur was formed by similar reactions, arguing that the hydrocarbons must be necessary by-products.

Sir Archibald Geikie communicated two most important papers on the results of Geological Survey work in the North-western Higlands. One of these papers, relating to the discovery of the *Olenellus* zone in the North-west Highlands, was as follows :—"Ever since the Geological Survey began the detailed investigation of the structure of the North-west Highlands of Scotland, the attention of its officers has been continuously given to the detection of any fossil evidence that would more clearly fix the geological horizons of the various sedimentary formations which overlie the Lewisian gneiss. A large collection of organic remains has been made from the Durness limestone, but it has not yet yielded materials for a satisfactory stratigraphical correlation. The study of this collection, however, has confirmed and extended Salter's original sagacious inference that the fauna of the Durness limestone shows a marked North American facies, though, according to our present terminology, we place this fauna in the Cambrian rather than in the Silurian system. Below the Durness limestone lies the dolomitic and calcareous shaly group known as the 'Fucoid beds,' which, though crowded with worm-castings, has hitherto proved singularly devoid of other recognizable organic remains. In following this group southwards through the Dundonnell Forest, in the west of Rosshire, my colleague, Mr. John Horne, found that, a few feet below where its upper limit is marked by the persistent band of 'Serpulite grit,' it includes a zone of blue or almost black shales. During a recent visit to him on his ground, when he pointed out to me this remarkable zone, I was struck with the singularly unaltered character of these shales, and agreed with him that if fossils were to be looked for anywhere among these ancient rocks, they should be found here, and that the fossil-collector, Mr. Arthur Macconochie, should be directed to search the locality with great care. The following week this exhaustive search was undertaken, and Mr. Macconochie was soon rewarded by the discovery of a number of fragmentary fossils, among which Mr. B. N. Peach, who was also stationed in the district, recognized what appeared to him to be undoubtedly portions of *Olenellus*. The importance of this discovery being obvious, the search was prosecuted vigorously, until the fossiliferous band could not be followed further without quarrying operations, which in that remote and sparsely inhabited region could not be at that time undertaken. The specimens were at once forwarded to me, and were placed in the hands of Messrs. Sharman and Newton, Palæontologists of the Geological Survey, who confirmed the reference to *Olenellus*. More recently Mr. Peach and Mr. Horne, in a renewed examination of the ground, have found, in another thin seam of black shale interleaved in the 'Serpulite grit,' additional pieces of *Olenellus*, including a fine head-shield with eyes complete. There may be more than one species of this trilobite in these Rosshire shales. The specific determinations and descriptions will shortly be given by Mr. Peach. The detection of *Olenellus* among the rocks of the North-west Highlands, and its association with the abundant *Salterella* of the 'Serpulite grit,' afford valuable materials for comparison with the oldest Palæozoic rocks of other regions, particularly of North America. The 'Fucoid beds' and 'Serpulite grit,' which intervene between the quartzite below and the Durness limestone above, are now demonstrated to belong to the lowest part of the Cambrian system. The quartzites are shown to form the arenaceous base of that system, while the Durness limestones may be Middle or Upper Cambrian. On the other hand, the Torridon sandstone, which Murchison placed in the Cambrian series, can now be proved to be of still higher antiquity. The marked unconformability which intervenes between it and the overlying quartzite points to a long interval having elapsed between the deposition of the two discordant formations. The Torridon sandstone must therefore be pre-Cambrian. Among the 8000 or 10,000 feet of strata in this group of sandstones and conglomerates, there occur, especially towards the base and the top, bands of grey and dark shales, so little altered that they may be confidently expected somewhere to yield recognizable fossils. Already my colleagues have detected traces of annelids and some more obscure remains of other organisms in these strata. These, the oldest relics of life yet known, have excited a vivid desire in the Geological Survey to discover further and more determinable fossils associated with them in the same primæval resting-place. We shall spare no pains to bring to light all that can be recovered in the North-west Highlands of a pre-Cambrian fauna."

In the other paper the Director-General dealt with some recent work of the Geological Survey in the Archæan gneiss of the North-west Highlands. "For some years past," he remarked, "the officers of the Geological Survey have spent much time and labour upon the investigation of the old or fundamental gneiss of the North-west Highlands. They have succeeded in showing that it consists mainly of materials which were originally of the nature of eruptive igneous rocks, but which by a long succession of processes have acquired the complicated structures which they now present. No evidence of anything but such eruptive rocks had been met with until the mapping was carried into the west of Rosshire. In that area it had long been known that the gneiss includes some mica-schists and limestones which were generally believed to be integral parts of its mass. With the accumulated experience of their work farther north, my colleagues were naturally pre-disposed to accept this view, and to look on even the limestones as the result of some crushing down and re-formation of basic igneous rocks containing lime-silicates. But as they proceeded in their work they encountered various difficulties in the acceptation of such a theoretical explanation. In particular, they found that with the mica-schist were associated quartz-schists and graphitic schists, and that the limestone occurred in thick and persistent bands with included minerals like those found in the Eastern Highlands in districts of contact-metamorphism. The microscopic examination of some of these rocks showed them to present close affinities to certain members of the crystalline series of the Eastern and Central Highlands, which can be recognized as consisting mainly of altered sedimentary strata (Dalradian series). Yet the officers of the Survey could not separate these doubtful rocks from the surrounding gneiss. The several materials seemed to pass insensibly into each other in numerous sections, which were examined with great care. Within the present month, however, one of the members of the staff, Mr. C. T. Clough, who has been specially engaged in this investigation, has obtained what may prove to be conclusive evidence on the subject. He has ascertained that the main bands of graphitic schist occur evenly bedded in an acid mica-schist, in which, also, thin graphitic layers are distributed at intervals of an inch or less. These rocks are sharply marked off from the true gneiss, though, where they actually join, they appear to be, as it were, crushed along a line of intense movement. Mr. Clough and his colleagues are at present disposed to believe that these schists are really an older series of sediments, into which the original igneous rocks now forming the gneiss were erupted. If they succeed in demonstrating the correctness of this inference, they will have established a fact of the highest interest in regard to the geological history of our oldest rocks. Already they have shown the thick masses of Torridon sandstone to be an accumulation of sedimentary materials of pre-Cambrian age. They will push back the geological record to a still more remote past, if they can establish the existence of a yet more ancient group of sedimentary strata among which layers of graphite and beds of limestone remain to suggest the former existence of plant and animal life."

The session on Monday was opened by Sir R. S. Ball with a paper on the cause of an Ice age. This communication stated that the author had a work in the press dealing with the question of glacial climates. He had revised Herschel's figures, on which Croll's deductions were based, and discovered an arithmetical error of considerable consequence. If 63 represents the number of heat-units received by any hemisphere during summer, its winter receipt will be represented by 37. Consequently, during a period of high eccentricity the 63 units of heat may be received in 199 days or in 166 days, according to the position of the equinoxes, producing either a long and cool summer or a short and intensely hot one. The paper did not deal with geographical considerations, and advocated the occurrence of clusters of alternate glacial and interglacial periods at each phase of high eccentricity in the earth's orbit. This paper excited considerable discussion, in which Prof. Sollas, Prof. Wright (of Oberlin, Ohio), Mr. Hall, Dr. Crosskey, Dr. Hicks, and many other glacialists took part.

Dr. Crosskey followed with his Report on the Distribution of Erratics in England and Wales, in which he referred to the useful work done by the North of England Boulder Committee, in systematically surveying the north in search of boulders and groups of boulders. Details were given of boulders from Lancashire, Cheshire, Derbyshire, Staffordshire, and Yorkshire, and it was remarked that boulders were being destroyed so rapidly that many described in former reports had totally disappeared. In another paper the same author controverted a statement of Forbes with regard to the glaciation of the Dovrefjeld. Wherever the basement rock is to be seen, it is glaciated, although morainic deposits were swept away and redistributed by torrential action at the close of the Glacial period.

Prof. Wright read a most interesting paper on the Ice age of North America and its connection with the appearance of man in that continent. The glacial deposits, transported from several centres mostly outside the Arctic circle, and the absence of a Polar ice-cap, militated against an astronomical, and for a geographical, cause of the great cold, particularly as an uplift of the glaciated area was coincident with an important subsidence in Central America. The author regarded the so-called "terminal moraine of the second period" as a moraine of retreat due to the first glaciation, and thought the evidence of forest beds, mainly to the south of the area, indicated local recessions of ice, and not a single great interglacial epoch. Palæolithic remains similar to those of the Somme and Thames have been found in several gravel terraces flanking streams which drain from the glaciated region, and made up of glacier-borne detritus; they are regarded by the author as deposits of the floods which characterized the closing portions of the Glacial period. The recession of the falls of Niagara and St. Anthony gives an antiquity of not more than 10,000 years to the end of the Glacial epoch—a conclusion supported by the enlargement of post-Glacial valleys and the silting up of small post-Glacial lakes.

Other papers read on this day were: one by Dr. Hicks, who produced specimens of boulders from Pembrokeshire, which seemed to him like North Welsh or Irish rocks—his picrite was, however, recognized as an Irish rock by geologists in the room, and in any case a flow of ice down the Irish Sea and over Pembrokeshire seemed to be clearly proved; one by Mr. Kendall, on a glacial section at Levenshulme, Manchester, in which he gave evidence from the striation of the subjacent rock, and the intrusion of tongues of boulder-clay into it, the transport of fragments, the orientation of large boulders, and the direction of striæ, together with a consideration of the levels of the different portions of the rock beneath, that the district had been traversed by land ice coming from a direction a few degrees north of west; and one by Mr. Bolton on a group of boulders from Darley Dale, near Matlock, which he regarded as having been washed out of rocks skirting the valley. In connection with these papers may be mentioned a report by Mr. Harrison, who has excavated in the talus under some rock-shelters at Oldbury Hill, near Ightham, from which he obtained forty-nine well-finished Palæolithic implements and over 600 waste flakes, which were described in a separate paper by Prof. Prestwich. Prof. Wright gave also a brief account of the basaltic lava beds of the Pacific coast, which are of post-Tertiary age. New evidence in favour of the genuineness of the Calaveras skull and other human remains found under the lava beds was given; and the discovery of a small clay image in a similar position under the western edge of the lava plains of Idaho at Nampa was recorded; the lava beds are correlated with the glacial deposits of the East.

Mr. Jones's report on the Elbolton cave, near Skipton, was of unusual interest. Long-headed human skulls were found with burnt bones and charcoal in the upper stratum, associated with domestic animals and pottery ornamented with diamond and herring-bone patterns; while at a much lower level—13–15 feet below the floor—there were round skulls, much more decayed, in connection with ruder and thicker pottery than has been found in any other part of the cave. No flints or metal of any kind have been found, and bone pins and other worked bones are the only human implements hitherto discovered. The remains of bear and hare have been found in cave earth below this level, and the investigation is to be continued in the hope that remains similar to those of the Ray Gill fissure may yet be met with.

An interesting discussion was raised on the paper by Dr. Hicks on the Silurian and Devonian rocks of Pembrokeshire and Devon. The Silurian rests transgressively on Ordovician and pre-Cambrian rocks in Pembrokeshire, but is covered by a continuous series up into the Old Red Sandstone and Carboniferous; similarly the Morte Slates, which the author regards as the oldest rocks of North Devon, and in which he has recently found *Lingulella Davisii*, are covered by the Devonian and Culm series of rocks. Mr. Ussher described the occurrence of a volcanic series in the Lower Devonian rocks of Tor Cross, and traced similar diabasic rocks amongst the chloritic series of Prawle Point, the excessive alteration of these rocks being due to the greater nearness to the old resisting rocks of the Channel. In this conclusion he was supported by Mr. Hunt, who described the occurrence of detrital tourmaline in the Devonian cliffs at the north-east end of Straiton Sands, and compared it with the occurrence of similar material in a quartz-schist west of the Start Lighthouse. Both schists and sandstone contain detrital tourmaline, mica, fine-grained quartz, and iron.

Several palæontological papers were contributed. Mr. Montagu Browne exhibited teeth, scales, and bones of Colobodus from Aust, Watchet, and Leicestershire, which seemed to indicate the identity of Colobodus with Lepidotus, and possibly of Heterolepidotus with Eugnathus, and to give Colobodus an extended upward range. Mr. Buckman gave an account of the Ammonite zones in the Inferior Oolite. There is a marked break on the Continent between the *Murchisonæ* and the *Sowerbyi* zones, which appears to be filled up by the zone of *Lioceras concavum* in England. The *Sowerbyi* zone, however, is absent in England from all localities except Dundry, and Coombe near Sherborne; and the author therefore sought and obtained a grant to open an old quarry at the latter locality, in order to fully investigate the fauna of the *Sowerbyi* zone, and its relationship to the *concavum* and *Sauzei* zones. Mr. Storrie, of the Cardiff Museum, exhibited a fine series of slides and drawings of *Pachytheca* and *Nematophycus*, and gave a minute description of them; this elicited some discussion, in the course of which Mr. Murray suggested that the former might possibly be the egg of a Crustacean or some other small organic body completely incrusted by a Nullipore. Mr. Smith Woodward exhibited Pterodactyl and Plesiosaur bones from Brazil, and gave an account of a series of Miocene fish-remains from Sardinia. Other palæontological papers were one containing a record of the occurrence of a variety of *Estheria minuta* in the Lower Keuper building-stone of Chester, by Mr. De Rance, and one by Mr. Vine on the Bryozoa of the Upper Chalk. Mr. B. Thompson gave an exhaustive report of the transition bed between the Middle and Upper Lias in Northamptonshire, from which he had obtained a large and valuable series of fossils. Mr. Newton described the occurrence of *Ammonites jurensis* in the Northampton sands, near Northampton; and Prof. Hoyes Panton gave an account of a mastodon of very large size at Highgate, Ontario, and a mammoth from Shelburne, in the same province.

The occurrence of a strip of Lower Greensand four to five miles long between Shaftesbury and Child Okeford, and running parallel to the valley of the Stour, was described by Mr. Jukes Browne. The same author attempted to explain monoclinal flexure by the recurrence of movement in rocks already faulted, but covered subsequently by unconformable strata; movement along the faults of the older series, under the influence of new pressure, would throw the overlying series into monoclinal folds or faults. The existence of a large area of Kellaways rock, near Bedford, and the extension of Fuller's-earth works at Woburn were commented on by Mr. Cameron.

Several of the Committees appointed last year had done good work. The Photograph Committee had obtained over 250 new photographs of geological interest, many of which were exhibited in the Section-room or at one of the *soirées*, where also Prof. Wright displayed a fine series of transparencies illustrating the lava and glacial deposits of the United States, and Mr. Stirrup a set of slides of the dolomite district of Languedoc. The Earth-Tremor Committee had been testing a number of recording-instruments; Mr. Smith Woodward reported that the lists of type specimens were progressing, and that many large Museums were publishing their own lists of types; Mr. De Rance gave an account of a number of wells in Yorkshire, Lincolnshire, Notts, Cheshire, Shropshire, and Glamorganshire; and Mr. Johnston-Lavis sent a description of the Vesuvian eruption of 1890–91, the chief part of which has already appeared in the columns of NATURE.

BIOLOGY AT THE BRITISH ASSOCIATION.

THE papers read at this Section were fully as interesting, though not quite so numerous, as usual. A good deal of time on one day was occupied by a discussion upon animals and plants; but as several of those who took part in the discussion did not wish their remarks to be reported, it has been thought better to leave out this part of the proceedings of Section D. Botanical papers preponderated over zoological, but it was not found necessary to divide the Section into two sub-Sections.

Mr. Grenfell read a paper upon the structure of Diatoms, describing pseudopodia in these organisms. The pseudopodia are quite easy to see in such a form as *Melosira* with even a comparatively low power. They are very long and stiff, radiating outwards from the periphery, and are apparently non-retractile (they were watched for an hour without any movements being observed); the pseudopodia are sometimes nine times the length of the diameter of the Diatom, and are occasionally branched; adjacent Diatoms were sometimes seen to be connected by a fusion of their pseudopodia. It was suggested that the use of the pseudopodia is to keep the plants floating, and to act as a protective *cheveux de frise* against their enemies. These Diatoms were compared to Heliozoa, with which they have evidently not a little resemblance in the form of the pseudopodia. Incidentally Mr. Grenfell stated that he had found a coating of cellulose upon the green corpuscles of *Archerina*, which were regarded by Lankester as chlorophyll bodies, and not as symbiotic algæ.

Mr. Wager described the presence of nuclei in Bacteria; they were met with in a species of *Bacillus* found in water containing decaying *Spirogyra*.

Dr. Gilson read a paper upon the nephridia of the leech, *Nephelis*. The ciliated funnels appear to lose their connection with the rest of the nephridium, and to perform the function of organs for the propulsion of the blood along the channels in which they lie.

The Plymouth Zoological Station sent a record of work done during the last year by the Director and by Mr. Cunningham.

Mr. Calderwood read a paper upon some economical investigations which had been carried out. He stated that three investigations had been started within the present year, which it was hoped would prove of great value to the fishing population of this country. One was an attempt to produce an artificial bait for use in long line fishing. This investigation was being carried on by a competent chemist, and a considerable advance had already been made towards a satisfactory solution of this difficult problem. Inquiries were also being conducted with regard to the occurrence of anchovies on the south-west coast of England, and Mr. Cunningham, the Naturalist of the Association, had carried out some inquiries at fishing stations on the south coast. At present no net small enough in the mesh to capture anchovies was employed, but that fish appeared so often when the ordinary pilchard nets became entangled, as to suggest that they might be present in considerable quantities. Anchovy nets had, therefore, been constructed, and would be used during the pilchard season this autumn. An investigation was also being carried on into the condition of the North Sea fisheries, which were declared to be rapidly declining. It was proposed to draw up a history of the North Sea trawling grounds, comparing their present condition with their condition some twenty or thirty years ago, when comparatively few boats were at work; to continue, verify, and extend observations as to the average sizes at which prime fish, such as soles, turbot, and brill, become sexually mature, and to collect statistics as to the sizes of all fish captured in the vicinity of the Dogger Bank and the region lying to the eastward, so that the number of immature fish annually captured may be estimated. Also to make experiments with beam trawl nets of various meshes with a view to determine the relation, if any, between the size of mesh and the size of fish taken. Mr. Calderwood added that a regular survey of the English Channel had been commenced, not only in the deep water, but in various estuaries. A meteorological station of the second order had been recently established, where observations at 9 a.m. and 9 p.m. would be taken daily by wet and dry bulb thermometers, barometers, rain-gauges, and sunshine-recorders.

Mr. J. T. Cunningham read a paper upon the reproduction of the pilchard. The ovum of this fish, described as such in the Journal of the Association for 1889, was stated by Pouchet not to belong to the pilchard; Pouchet believed that the pilchard's ovum is not pelagic. The identification of the ovum was shown to be correct by further observations carried out in the Laboratory with the ova obtained from the mature fish. Similar results have been obtained by Marion, of Marseilles.

Another paper, by the same, dealt with the growth of food-fishes, and their distribution at different ages.

(1) *Rate of Growth and Age of Sexual Maturity.*—Numerous specimens of the flounder (*Pl. flesus*) were reared from the larval state in the aquarium of the Plymouth Laboratory. Measured in April, when a year old, they varied from 4 to 19 cm. (about 1½ to 7½ inches). Specimens obtained in the Cattewater, and known to be not less than a year old, are from 12 to 19 cm. in length. None of these captive flounders, nor any taken in the Cattewater, were sexually mature, but, according to Dr. Fulton, of the Scottish Fishery Board, sexually mature flounders have been observed which were only 7 inches long. It was concluded, therefore, that (*a*) the rate of growth varies greatly for different individuals, but its maximum for the first year is 19 cm., or 7½ inches; (*b*) sexual maturity is not reached till the end of the second year, although the minimum size of sexually mature individuals may be slightly exceeded by some specimens in one year's growth.

Similar results were obtained for the plaice (*Pl. platessa*) and the dab (*Pl. limanda*).

(2) *Distribution.*—The young of the above-mentioned species in their first year, and of certain round fish, especially *Gadus luscus* and *G. minutus*, occur in shallow water, within the 10-fathom line. But there has hitherto been considerable difficulty in obtaining young specimens of other more valuable species in order to study their rate of growth. These species—namely, the sole, turbot, brill, lemon sole, megrim (*Arnoglossus megastoma*), do not pass the first year of their lives in shallow water. Young soles in the larval state occur in tidal pools at Mevagissey, and young turbot and brill 2 to 3 cm. in length are commonly found from June to August in Plymouth Sound and Sutton Pool, swimming at the surface in a semi-metamorphosed stage. Soles a little over 16 cm. in length are frequently taken in Plymouth Sound in summer; these are just over one year old, and are not sexually mature. Turbot 23 to 34 cm. long may be taken in 5 to 7 fathoms; these also are over one year old and not sexually mature. But the young stages between 3 months and 12 months old have not been taken in shallow water, and apparently live at depths greater than 10 fathoms. It seems that our commoner and more valuable food-fishes do not attain to sexual maturity till the end of their second year, that their size at this age is subject to great individual variation, and that the young in the first year of growth have a characteristic distribution. Investigation of the deeper water from this point of view is now being carried on at Plymouth.

The distribution of *Crystallogobius Nilssoni* was recorded by the same author. It had been found by Collett in the Christiania Fjord and in other parts of Norway; also at Bohuslan, in Sweden. Mr. Cunningham dredged 100 specimens at a single haul close to the Eddystone, in 27 fathoms of water. Day mentions only one specimen found in British waters—one taken by Thomas Edwards in a rock pool at Banff. Mr. Holt subsequently dredged a number in 30 fathoms in Ballinskelligs Bay. The species is probably fairly abundant between 20 and 30 fathoms on smooth sandy ground all along the British and Irish coasts.

Mr. Cunningham also read a paper upon the larvæ of the sea crayfish (*Palinurus vulgaris*), describing most of the stages, and particularly remarking upon the presence of the first maxillipede in the newly hatched larva, which had been stated by Richter to be absent.

Prof. Herdman and Mr. J. A. Clubb communicated a paper upon the innervation of the epipodial processes of some Nudibranchiate Mollusca. The cerata of the Nudibranchs were regarded by Prof. Herdman as being probably epipodial outgrowths.

The question has, however, been raised lately by Pelseneer and others as to whether the so-called epipodia of Mollusca are all homologous structures, and one of the subjects of controversy now is the origin of the nerve supply in various forms, it being supposed that where the processes are innervated from the pleural ganglia they are pallial in their nature, and where supplied from the pedal ganglia they are to be regarded as outgrowths from the foot.

Consequently it seemed of importance to determine afresh the origin of the nerves supplying the cerata in several different types of Nudibranchiata, especially as the results of former investigations, depending entirely, we believe, upon minute dissection, are puzzling, and to some extent contradictory. We have traced the nerves from the ganglia, by means of serial sections, in representatives of the genera *Polycera*, *Ancula*, *Tritonia*, *Dendronotus*, and *Eolis*, with the following results:—

In *Polycera quadrilineata* the cerebral and pleural ganglia are completely fused to form a cerebro-pleural mass. The "epipodial" nerves are found arising from the ventral and posterior part of this mass (*i.e.* distinctly from the pleural ganglia), and they run along the sides of the back to supply the ceratal ridges.

In *Ancula cristata* the pleural ganglia are fairly distinct from the cerebral. In a specimen cut into about 500 sections we find in the 100th section or so from the anterior end six distinct ganglia (the cerebral, pleural, and pedal pairs) surrounding the œsophagus. A few sections further back, the cerebrals disappear, and then the epipodial nerves are found arising from the dorsal edge of the pleural ganglia. The nerves soon turn posteriorly, and then give off their first branches dorsally. These branches enter the mesoderm of the body wall, and can then be traced back through over a hundred sections to the first pair of cerata, which they enter. The main nerve passes back to the remaining cerata.

In *Tritonia* and *Dendronotus* also the epipodial nerves arise from the pleural ganglia; but in *Eolis* (or *Facelina*) *coronata* we find that the main nerves to the cerata arise distinctly from the pedal ganglia. We have also traced in the same series of sections the ordinary pedal nerves to the foot proper; so there can be no question as to the nature of the ganglia from which the nerves arise. The epipodial nerves spring from about the middle of the pedal ganglion, rather on the dorsal surface, and, after a short course, pass through the muscular layer of the body wall and are distributed to the clumps of cerata.

But, in addition to these main epipodial nerves in *Eolis*, we find also a nerve arising from the compound ganglionic mass, immediately ventral to the eye (probably, therefore, from the pleural element), which goes to the front cerata. This pleural nerve has its origin distinctly anterior to the origin of the main epipodial nerves from the pedal ganglia.

We arrive, then, at the curious result that the innervation of the ceratal processes is not the same in all these Nudibranchs. In *Polycera*, *Ancula*, *Tritonia*, and *Dendronotus*, the epipodial nerves arise from pleural ganglia, or from the ventral and posterior parts of cerebro-pleural masses; while in *Eolis* the chief epipodial nerves are from the pedal ganglia, but there are also smaller nerves from the pleurals. In the ordinary Rhipidoglossate Gastropod, such as *Trochus*, the epipodial ridges and processes are supplied, according to Pelseneer, by nerves arising from the dorsal part of the elongated pedal ganglia. So, judging from the nerve supply alone, it might be said that the cerata of *Eolis* are pedal in their nature, and homologous with the epipodial processes of *Trochus*, while those of *Ancula* and the rest are totally distinct structures of pallial origin. But these dorso-lateral processes in the various Nudibranchs are so much alike in their relations, and are connected by such series of gradations, that it is difficult to believe that they are not all homologous; and the presence of the accessory epipodial nerve in *Eolis* arising from the pleural ganglion suggests the possibility of another explanation, viz. that these outgrowths, starting at first as pedal structures innervated by nerves from the pedal ganglia, may have acquired, possibly as the result of having moved further up the sides of the body, a supplementary nerve supply from the adjacent integumentary nerves arising from the pleural ganglia, and this supplementary supply, while remaining subordinary in *Eolis*, may in the other types have gradually come to supplant the original epipodial nerves, which are now no longer found in such forms as *Polycera* and *Ancula*. This is at present only a suggestion, which may be disproved or supported by the examination of the nerves of a number of additional Nudibranchs.

Prof. W. N. Parker read a paper containing the results of some experiments on respiration in the tadpoles of the common frog. After referring to the great power of adaptation to external conditions seen amongst amphibious larvæ, the author described some experiments on frog tadpoles, which, although not yet complete, show as follows:—(1) Soon after the lungs become functional—*i.e.* in tadpoles measuring more than 2 cm.

in length—the gills are no longer sufficient for purposes of respiration, and the animals die in a very short time if prevented from coming to the surface to breathe. (2) If tadpoles are prevented from using their lungs from an earlier stage onwards, the gills remain perfectly functional, and development proceeds as usual. At metamorphosis, the fore-limbs are slow in becoming free, owing to the retention of the operculum, that on the same side as the spiracle appearing first. Eventually, a slit-like spiracle is present on either side. In respiration, the mouth is opened and closed, as in the tadpole. Specimens of branchiate frogs were exhibited, in which the tail had shrunk to less than half its original length.

Exhibition of, and remarks upon, some young specimens of *Echidna aculeata*, by Prof. W. N. Parker. The specimens are from the collection of the late Prof. W. K. Parker, who received them from Dr. E. P. Ramsay, Curator of the Australian Museum, Sydney. They are much curved towards the ventral side, the snout pointing backwards, and the tail, in the older of the two stages, forwards. The younger stage measures along the dorsal curve, from the end of the snout to the tip of the tail, 12 cm., the greatest diameter of the body being 3 cm.; the corresponding measurements of the older stage are respectively 21·5 cm. and 6 cm. In the latter, the body is covered with short scattered bristles. In both stages the snout is very similar in form to that of *Ornithorhynchus*, and is covered by a thick horny layer, but in other respects the specialization characteristic of *Echidna* is already apparent. The gape is narrow, and extends only a short distance down the snout, and the manus, even in the younger stage, is already much larger and stronger than the pes. The tail is short and conical. There is no caruncle, or "egg-breaker," in the snout, such as is seen in *Ornithorhynchus*. A few points in the structure of the fore-part of the head in the older stage were described. The mouth has the narrow and tubular form seen in the adult, and the long tongue has a horny tip. The glands in relation with the mouth and nose are very numerous. There is no trace of any teeth-rudiments, and in many other respects the structure of the head shows extreme specialization. Jacobson's organ is large, and highly developed. A well-marked "turbinal" is present in it.

Prof. Howes read a paper upon the classification of fishes by their reproductive organs. On comparison of the urino-genital organs of those Osteichthyes having a non-abbreviated kidney with the same organs of the higher Vertebrata and the Elasmobranchs, the female genital duct and the kidney are seen to be inversely proportionate in length. No feature more fully characterizes the development of the Müllerian duct than the accompanying abbreviation of the kidney and the disappearance of its head segment. The persistence of the last-named among the Osteichthyes, and its possible retention of the renal function in rare cases, taken in conjunction with the mode of development of the ovary duct in these fishes, point to the conclusion that the latter is in no way homologous with the Müllerian duct as ordinarily understood. Balfour's belief that the genital ducts are homologous in both sexes of the Teleosteans, is supported by the facts of anatomy; and comparison of the reproductive system of the Ganoids with that of the Teleosteans shows the two to be modifications of the same common type; and the absolute structural community of the parts in the males and females of the Sturiones, while further confirming Balfour's doctrine, is opposed to Jungersen's implication that the subtle differences in the mode of development of the ducts in the opposite sexes of the Teleostei, are indicative of their non-homology. The facts above alluded to justify us in regarding the genital ducts of the Osteichthyes, not only as homologous in the two sexes, and primarily independent of the genital glands, but as distinct structures *sui generis*, probably unrepresented in all other Vertebrates. The Plagiostomi and Holocephali, in which vasa efferentia are present and the kidney becomes an accessory to reproduction in the male, may be grouped together into a *Nephrorchidic Series*, as distinguished from an *Enthorchidic Series*, embracing the Ganoids and Teleosteans. Comparison of the pori genitales in relation to the coalesced ureters of the Marsipobranchii with the corresponding parts of the females of those Teleostei destitute of genital ducts, especially in consideration of the facts concerning the development of the parts recorded by Scott, Liszt, and others, supports Rathke's conclusion that the ancestors of the former fishes must have possessed genital ducts. The Osteichthyes, although specialized in respect to many features of their organization, have, together with the Marsipobranchs, retained the least modified type of urinogenital organs known for living Vertebrates. W. N. Parker's recent and important discovery that, while in *Protopterus* a Müllerian duct is present, vasa efferentia are absent, and the testicular products are discharged through a duct more nearly comparable to that of the bony fishes than to the genital ducts of any other Vertebrates, suggests that the development of vasa efferentia and the assumption of a genital function by the Wolffian duct may have been effected subsequently to the formation of the Müllerian oviduct. And further comparison of the Dipnoi with the Elasmobranchii suggests that the former may have struck off from the Holocephalic branch of the latter before the differentiation of the ancestors of its living members.

Another paper by Prof. Howes dealt with the customary methods of describing the gills of fishes. The gills of Plagiostomes and Marsipobranchs are not unfrequently enumerated in relation to the opposite walls of the visceral sacs which give origin to them, while those of the higher fishes are enumerated in relation to the opposite faces of the septa which bear them. The confusion arising out of this is well known to teachers, and is, in itself, sufficient to justify the introduction of a revised nomenclature for the parts concerned. The facts of development show: (1) [on the assumption that the mandibular or mouth cavity is serially homologous with a pair of post-oral visceral clefts] that each gill lies in front of its corresponding skeletal arch; (2) that the saccular type of gill met with in the Marsipobranchs and Plagiostomes is that from which the pectinate one of the higher gnathostomatous fishes has been derived; and (3) that a mandibular gill has no existence in living fishes. Gills of the Marsipobranch-Plagiostome type may be conveniently described for general anatomical purposes, as *Cystobranchiæ*, and those of the higher Telosteoid type, as *Pectinobranchiæ;* while the parts of the individual gills themselves should be in all cases enumerated in relation to the visceral pouches from which they arise. Thus, the spiracular gill of Elasmobranchs (often termed the mandibular pseudobranch) should be described as the hyoid hemibranch, and the opercular gill of the higher fishes (often termed the hyoid pseudobranch) as the first branchial hemibranch. The well-known series of buccal filaments met with in certain Chelonia appear to have the fundamental relationships of gill-folios, and, in view of the discovery of Dohrn and others that the buccal sac would appear, from its mode of development in the Teleostei, to be the morphological equivalent of a pair of gill pouches, the possibility that these filaments may (at any rate for the most part) represent mandibular gills of a reversional character must not be overlooked.

Dr. Arthur Robinson communicated some facts relative to the development of the rat and the mouse. The most important part of the paper dealt with the relation of the yolk sac to the maternal tissues. The crypt in the uterine wall which lodges the ovum becomes shut off from the rest of the cavity of the uterus by a fusion between the distal proximal walls of the uterus. The greater part of the space so formed is occupied by the ovum; the remaining portions are converted into maternal blood sinuses; the blood in these sinuses bathes the trophoblast and the distal end of the yolk sac. Later, the distal part of the yolk cavity is obliterated by the apposition of its walls, but the proximal portion remains; diverticula grow out from from this into the placenta, which maintain the intimate relation of the yolk sac to the maternal blood. It seems probable, in view of these facts, that the yolk sac plays an important part in the nutrition of the fœtus. The allantois is a solid mass of mesoblast containing no diverticulum from the alimentary tract, and does not become attached to the trophoblast until comparatively late in the life of the embryo, *i.e.* the eleventh day.

Another paper by the same was entitled "Observations upon the Development of the Spinal Cord in *Mus musculus* and *Mus decumanus:* the Formation of the Septa and the Fissures." The anterior and posterior septa of the cord were stated to be formed by the spongioblasts of the cord itself, and not by ingrowths of the enveloping sheath of pia mater.

Prof. Marcus Hartog communicated an outline classification of sexual and allied modes of protoplasmic rejuvenescence.

I. The following modes of rejuvenescence occur in cellular and in certain apocytial organisms:—

A. PLASTOGAMY: the fusion of cytoplasta into a plasmodium, the nuclei remaining free.

B. KARYOGAMY: the union of cells (gametes), cytoplast to cytoplast and nucleus to nucleus, to form a 1-nucleate cell, the zygote. The following variations occur:—

1. ISOGAMY. The union of gametes undistinguishable in size, form, and behaviour; this may vary as follows:—
    - (*a*) MULTIPLE: between several gametes (up to 6).
    - (*b*) BINARY: between a pair of gametes;

    or, from another point of view—
    - (*c*) INDIFFERENT: between any gametes of the species.
    - (*d*) EXOGAMOUS: between gametes of distinct broods only.
    - (*e*) ENDOGAMOUS: between gametes of the same brood only.
2. ANISOGAMY: the union of two gametes differing chiefly in size; the smaller (*micro-*) gamete is *male*, the larger (*mega-*) gamete, *female*.
3. HYPERANISOGAMY: the female gamete, at first active, comes to rest before fusion with the male.
4. OOGAMY: the female is never actively motile; the male is termed a *spermatozoon*, the female an *oosphere*.

From another point of view karyogamy is—

5. ZOOIDIOGAMOUS: one gamete at least is actively motile (flagellate, ciliate, or amœboid).
6. SIPHONOGAMOUS: karyogamy is effected by a tubular outgrowth from one or both of the gametes.

II. In apocytial fungi multinucleated masses of protoplasm (*gametoids*) may conjugate to form a *zygotoid*, by a siphonogamous process. The union may be *isogamous* or *anisogamous*.

III. Gametes may be classified as follows:—

A. According to their *formation*—

1. EUSCHIST: formed by repeated complete divisions from a parent cell, the gametogonium.
    - (*a*) EUTHYSCHIST: each nuclear division is accompanied by cell division.
    - (*b*) BRADYSCHIST: the nuclear divisions are completed before any cell division takes place.
    - (*c*) ISOSCHIST: the brood-cells of a gametogonium are all equal and functional.
    - (*d*) ANISOSCHIST: the brood-cells are unequal, some of them being reduced to aborted or degraded gametes.
2. HEMISCHIST: the divisions are limited to the nucleus, none occurring in the cytoplasm.
3. APOSCHIST: the cell divisions do not occur, but a cell directly assumes the behaviour of a gamete.
4. SYMPHYTIC: the gameto-nucleus is formed by the fusion of several nuclei.

B. According to their *behaviour*, as—

1. FACULTATIVE: retaining the power of development if karyogamy fails to occur.
2. OBLIGATORY: with no power of independent development.

IV. PARAGENESIS will include the following modes, usually grouped under the term parthenogenesis, apogamy (*pro parte*), &c.:—

A. TRUE PARTHENOGENESIS: the direct development of a facultative gamete without karyogamy. This may occur in the case of—

(1) Isogametes; (2) Anisogametes (male and female); (3) Oogametes.

B. SIMULATED PARTHENOGENESIS:—

1. CELLULAR: a cell assumes directly the behaviour of a zygote.
2. APOCYTIAL: a multinucleate mass of protoplasm assumes directly the behaviour of a zygotoid.

C. METAGAMETAL REJUVENESCENCE:—

1. UNICELLULAR: a single cell in the neighbourhood of the gamete assumes the form and behaviour of the zygote.
2. MULTICELLULAR: a mass of cells in the position where gametes should be produced, assumes the character of the young organism formed by the zygote.

D. PARAGAMY or ENDOKARYOGAMY: vegetative or gametal nuclei lying in a continuous mass of cytoplasm fuse to form a zygote nucleus.

1. Progamic paragamy: the fusing nuclei are the normal gametonuclei of the progamous cell (ovum which has formed 1-polar body).
2. Apocytial paragamy: the vegetative nuclei of an apocytium fuse to form a zygote nucleus.

The President of the Section read a paper by himself and Miss Dorothea Pertz, on the artificial production of rhythm in plants. The apparatus, devised by the Cambridge Scientific Instrument Company, was exhibited. The plant is subjected to a series of alternate and opposite influences from light or gravitation, as the case may be. The plant to be experimented with is fixed to a spindle, which, by a clockwork escapement, makes a sudden semi-revolution every half-hour. When the clockwork is stopped, the plant continues to curve with an acquired rhythm, as if the machinery were still in action. This is similar to certain natural rhythms—for instance, to the "sleep" of flowers, which for a short time continue to open and shut although kept constantly in the dark.

Prof. Green read a paper on the occurrence of diastase in pollen. The starch in the pollen grain serves as nutriment for the growing pollen tube, and the presence of the ferment converting it into sugar enables it to travel along the growing tube.

Prof. Vines, in a paper upon diastase in foliage leaves, controverts the opinion of Prof. Wortmann, who stated that diastase was either absent from the foliage leaves of plants, or present in such minute quantities that it could be of no physiological importance. It is this diastase, and not the protoplasm of the cells, which converts the starch accumulated in the leaves into sugar.

Canon Tristram exhibited and made remarks upon the smallest known species of parrot, of which the skin measured only two inches in length.

THE CONGRESS OF HYGIENE.

WE printed on August 20 (p. 303) an account of some of the work done in the Section of Preventive Medicine in the Congress of Hygiene. The following is the conclusion of our report:—

ALCOHOLISM.

Sir Dyce Duckworth, of London, opened a discussion on "The Relation of Alcoholism to Public Health and the methods to be adopted for its Prevention."

Prof. Harald Westergaard, of Copenhagen, followed with a paper on the same subject. What are the losses of life, he asked, caused to a population by intemperance? This question can to a certain extent be answered by examining the causes of death, especially delirium tremens and chronic alcoholism. It has been objected that these causes of death supply an unsatisfactory picture of drinking excess, because the wish to spare the feelings of surviving relatives makes returns of such deaths less trustworthy, and it has therefore been proposed to use other diseases as a measure—such as liver disease (especially cirrhosis of the liver). Yet it is worth while to examine the above-mentioned causes of death. In most countries the statistics of the cause of death do not allow conclusions with regard to alcoholism corresponding to those for Denmark and Norway. But, at all events, the statistical data sufficiently show that a great part of the civilized world is suffering greatly from the effects of alcoholism. The investigations of the Harveian Society make it probable that in London one-seventh of all adult deaths (males and females) is directly or indirectly due to the consequences of alcoholic excess. The mortality in England from alcoholism in 1871–80 among males 25 to 65 years old was about 1 per cent. of all deaths—nearly 800 yearly. What an amount of disease and poverty, of moral and physical degradation, is represented by these 800 deaths! In Belgium the yearly loss of life from delirium tremens among males was 330 in 1870–89. Still greater have been the devastations of drinking in Switzerland. Prussia has a yearly loss of 1100 males from delirium tremens. Undoubtedly we should find, if trustworthy data could be had, that chronic alcoholism and delirium tremens alone kill many thousands of men every year. What is to be done? High excises are generally looked upon as an excellent weapon against alcoholism. But we must not forget that even a very high excise, as in England, does not prevent spirituous liquors from coming within the reach of anybody, so long as the number of public-houses is so exceedingly large as in this country. If a person has to go a long way to get drunk, and if he has in addition to pay a good sum for it, he will stop to think before going. Still, high excises seem to have some effect; the German law of 1887 has, for instance, reduced the consumption of spirits to a certain extent. But generally the reduction of the consumed quantity does not seem to correspond with the increase of the excise. An interesting expedient is the new State monopoly in Switzerland. Ten per cent. of the surplus are left to the cantons for counteracting alcoholism. By regulating the price the monopoly acts like an excise, and the Government takes care that only unadulterated liquors are sold. The monopoly is reported to have had a good sanitary effect, and it has caused some decrease in the consumption of liquors. In connection with excise and duties every effort is to be commended which tends to render the access to intoxicating liquors more difficult. Among these measures, the three popular American systems deserve our attention—viz. the Maine laws, local option, and the high-licence system. The first of these expedients—the prohibitory system—has been tried in Maine and some other American States. According to this system, it is prohibited to manufacture and sell intoxicating liquors, the only exception commonly being that liquors of "foreign production" may be imported and sold in the original packages. But this exception is unjust, permitting the man who can afford it to order as much liquor as he likes, and nearly all reports agree in testifying to the perpetual violation of these laws. One curious fact from Maine, where the system was adopted in 1881 may be mentioned. During the years 1867–86, 8412 divorces of marriages took place, being probably several per cent. of the yearly number of celebrated marriages. Of these no less than 960, or 11 per cent., were caused by intemperance, combined or not with other causes. It thus seems that intemperate habits are rather frequent in this State. Curiously enough, the State of Massachusetts (where there is a considerable revenue for licences) shows, under nearly the same regulations concerning divorces as in Maine, the same proportion—viz. 1054 out of 9853. It seems impossible to suppress the liquor traffic in the larger towns. Between the Maine laws and the high-licence system is an intermediate system—local option. According to this, it is left to the citizens of a village, town, city, or a larger district, to vote for local prohibition. This system seems to work somewhat better than the Maine laws, and it may prove useful in rural districts, the control in small communities being more easily carried through; but in larger towns it is probably ineffective, tempting as it does to a surreptitious liquor traffic. The third system—high licences—has been introduced in several States. Under this system licences for the sale of liquors can be taken out, but the fees are so considerable (for instance, 500 or 1000 dollars yearly) that many small saloons disappear. In some cases the sale of liquors through grocery stores is entirely stopped (Illinois). This system is reported to work well by reducing the number of drinking saloons, thus lessening the opportunity for drinking. It is maintained that "the high-licence system has thrown the liquor traffic into the hands of a more respectable class of dealers," and that those who pay high licences "help the authorities in the conviction of breakers of the law, under the fundamental principle of self-preservation." It is also to be recommended to limit the numbers of licences that may be taken out. This is the case with the Dutch law of 1881. Still more effective have been the efforts in Sweden, Norway, and Finland. The numbers of bars have been gradually greatly reduced, especially in the rural districts; and in most of the towns the so-called "Gothenburg system" has been introduced. According to this system, adopted since 1865 in Gothenburg, all or most of the licences in a town are given to a company which is not allowed to pay more than a fixed rate of interest to the shareholders, the surplus being spent for the benefit of charitable institutions or forming part of the municipal income. The result has been a great reduction of the number of bars. In Gothenburg the company in 1865 took out 40 licenses, but at once reduced the number of saloons to 23. The persons who manage the saloons get a fixed salary for the sale of spirits, and are therefore not tempted to encourage the customers to drinking. Moreover, there is a limitation of the hours during which the saloons are open, and other steps have been taken to prevent abuses. Undoubtedly this system—in connection with the great diminution of the number of bars in the rural districts of the country—has contributed very much to the conspicuous reduction of the alcoholism in the three countries before-mentioned. A very practical expedient is also the prohibition of sale of intoxicating liquors at groceries and similar shops, and this provision ought never to be omitted where steps are taken to limit the number of saloons. And last, not least, it is highly desirable to regulate the opening hours of the saloons.

Dr. Isambard Owen, of London, said he took part in the discussion solely to correct the numerous misquotations current of the "Collective Investigation Report on Intemperance of the British Medical Association," of which Report he was the author. A certain table of figures contained in the Report had been quoted apart from the context in such a manner as to lead the public to believe that, in the view of the author of the Report, the longevity of abstainers fell below that, not only of moderate drinkers, but even of the decidedly intemperate. The conclusions of the Report, as far as concerned the general health of the public, were the following:—(1) That habitual indulgence in alcoholic liquors, beyond the most moderate amounts, has a distinct tendency to shorten life, the average shortening being roughly proportional to the degree of indulgence. (2) That of men who have passed the age of 25, the strictly temperate live, on the average, at least ten years longer than those who become decidedly intemperate. (3) That in the production of cirrhosis and gout, alcoholic excess plays the very marked part which it has long been recognized as playing, and that there are no other diseases anything like so distinctly traceable to the effects of alcoholic liquors. (4) That, cirrhosis and gout apart, the effect of alcoholic liquors is rather to predispose the body towards the attacks of disease generally than to induce any special pathological lesion.

M. Milliet, of Berne, Dr. Norman Kerr, of London, Mr. J. Phillips, of London, Sir V. Barrington, L.C.C., Dr. Robinson, of Maine, U.S.A., Sir Joseph Fayrer, Prof. E. Alglave, of Paris, Dr. Kinkead, of Galway, Dr. Arthur, of London, Prof. Böhmert, of Dresden, and Dr. Sonsino, of Pisa, also took part in the discussion.

On Thursday afternoon, Dr. W. O. Priestley read a paper "On the Improved Hygienic Condition of Maternity Hospitals," of which the following is an abstract:—

During the end of the last century and the first half of the present one, the mortality in maternity hospitals was very large, both on the Continent and in Great Britain. According to Le Fort, it was at the rate of 34 per 1000, while, according to Miss Nightingale, it was only 4·7 per 1000 when patients were confined at their own homes; or, according to Dr. Matthews Duncan, 8 per 1000, equal to 1 in 125. The cause of the increased mortality in lying-in hospitals was the prevalence in these institutions of puerperal fever, 75 per cent. being due to this cause. The infectiousness of puerperal fever, long doubted, was at length established, and also the fact that various poisons, brought from the dissecting room—from patients suffering from erysipelas, eruptive fevers, and the like—became the germs of infection which might cost the lives of many patients. The researches of Pasteur, Koch, Lister, and others have shown that these poisons owed their virulence to the presence of microscopic germs which multiply in the body of patients and produce the deleterious results. Hence it came to be recognized that, by preventing the ingress of these germs to the bodies of puerperal patients, comparative safety, even in lying-in hospitals, was attainable; and the introduction of the antiseptic and aseptic methods has produced not only a remarkable diminution of mortality, but also of the morbidity or illness incident to the puerperal state. A short sketch was given of the modern methods adopted in several countries to insure the greater safety of patients in maternity hospitals, and of the results obtained in Europe and in the United States. The results were very striking, and were attributable mainly to the introduction of the antiseptic or aseptic modes of treatment, although other improvements are not lost sight of. In concluding he called attention to an interesting table in which were thrown together the statistics of maternal deaths in six lying-in hospitals, situated in various countries, since the introduction of aseptic or antiseptic methods. With these he had contrasted the figures of M. Le Fort before the era of antiseptics, and Mr. Newbatt, the distinguished President of the Statistical Society, had kindly computed for him the difference in the proportion of deaths in the two cases:—

Mortality in Maternity Hospitals from all Causes in various Countries of Europe (*Le Fort*).

BEFORE THE INTRODUCTION OF ANTISEPTICS.

	Deliveries.	Deaths.	Per 1000.
Total	888,312	30,394	34·21

AFTER THE INTRODUCTION OF ANTISEPTICS.

	Date.	Deliveries.	Deaths.	Deaths which would have occurred on basis of Le Fort's figures.
Vienna	1881–5	15,070	106	516
Dresden	1883–7	5,508	57	188
Russia	1886–9	76,646	290	2,622
New York ...	1884–6	1,919	15	66
Boston	1883–6	1,233	27	42
General Lying-in Hospital, London	1886–9	2,585	16	88
Total ...	—	102,961	511[1]	3,522

Number of lives saved out of the 102,961 since the introduction of antiseptics—

Expected deaths on Le Fort's basis	3522
Actual deaths	511
Saving	3011

Dr. Priestley said it would be seen that while, according to M. Le Fort, the maternal deaths in European lying-in hospitals were 34·21 per 1000 under the old *régime*, the mortality is now reduced to somewhat less than 5 per 1000. This computation, put in another way, indicates that if the former rate of mortality had been maintained 3522 maternal deaths might have been expected; the actual deaths were only 511. In other words, 3011 lives of mothers were saved as the result of new and purely scientific methods of treatment. This, he thought, might fairly be stated to be one of the most striking triumphs of preventive medicine. It was no mean achievement to rescue from death more than 3000 lives of women in the acme of their maturity, and when their lives were most valuable to their families.

Dr. Graily Hewitt, of London, Mr. F. Fowke, of London, and Dr. Leduc, of Nantes, spoke on the subject.

A paper was read by Dr. J. C. van Dooremal, of The Hague, on "La Prévention de la Cécité professionnelle."

Dr. Sisley, of London, read a paper on "The Prevention of the Spread of Epidemic Influenza."

Mr. Weaver and Dr. Felkin took part in the discussion.

Greene Pasha, of Cairo, read a paper on "The Influence of the Nile on Mortality in Egypt."

Dr. Felkin, of Edinburgh, read a paper entitled "Observations on Malaria and Enteric Fever in Central Africa, and on the possible Antagonism between Malaria and Phthisis."

Inspector-General Lawson and Mr. Weaver spoke on this subject.

Dr. Lewis Sambon, delegate of the Municipality of Naples, read a paper on "Measures adopted for the Prevention of Infectious Diseases and their Relation to our Knowledge of Epidemics." He first pointed out the similarity, which is most striking, between the mode of development and diffusion of infectious diseases and some insect pests, such as locusts for instance. Both have likewise their endemic areas, both their seasons of development, both in some years spread more widely, and at long intervals give rise to regular plagues; both migrate in the same constant direction, and both die away out of their endemic areas, subsiding in the struggle for life. He said that the diffusion of species by currents and winds will make us understand the peculiarities in the spread of infectious diseases, which had given rise, in all time, to the most strange theories. The influence of atmosphere has been very little studied in connection with infectious diseases, and by this he did not mean the registration of the prevailing lower winds during an epidemic, but serious bacteriological researches in the sinking sediment of the atmosphere and in meteoric waters. Instances of animals being carried by regular winds or wind-storms far beyond the limits of their homes are universally known. Insects of all kinds are often caught hundreds of miles from the nearest land, out on the high seas; North American birds not unfrequently are carried across the Atlantic to Scotland. Far more important is the influence of winds and currents in the distribution of microscopic animals. These minute organisms or their germs, generally adhering to other larger elements of dust, are raised and carried by the wind until they are allowed to sink again to the soil when the air is in stillness. About quarantine Dr. Sambon said that not only our modern investigations proved them useless, but that a long experience has utterly condemned them. England has been accused of being commercially and politically interested in the abolition of quarantine, and this preconception has unfortunately prevented many from valuing the most scientific and liberal ideas which have promoted their opposition to quarantine. No nation can boast of having held public health so high above commercial interest; and we must also remember that the English, at one time, have been the most sanguine supporters of quarantine. Quarantine was first instituted by the old republic of Venice, whose life and power lay entirely in commerce; and Dr. Sambon said that, although it had proved so disastrous to finance, so useless to sanitation, and so vexatious to liberty, he was proud that they were a glory of his country. Dr. Sambon concluded that the most important and perhaps the only satisfactory means against infectious diseases was the sanitation of towns and the hygiene of men. In speaking of the sanitation of towns he said how vast areas of the old city of Naples had been recently pulled down and new districts had been built. A large and splendid supply of water has been introduced since 1887, and when the drainage is completed, Naples will be one of the healthiest towns of Europe. He spoke of the poor classes of all our large towns, and said how they were the culture grounds of epidemics, and finished by saying that it is not enough to improve the sanitary conditions of a town, but that the principles of hygiene should be impressed on the minds and consciences of people, because there could be no public hygiene where private hygiene was not understood.

Deputy-Surgeon-General Bostock, C.B., and Sir Vincent Barrington, delegates of the Metropolitan Asylums Board, read a joint paper on "The Hospital and Ambulance Organization of the Metropolitan Asylums Board for the Removal and Isolation of Infectious Diseases." The paper was illustrated by plans, diagrams, and models.

Surgeon-General Bostock said that the present accommodation for fever and diphtheria consists of six hospitals:—

Name.	Position.	Acreage.	No. of beds.	Population served.
1. Eastern	Homerton	9	442	1,114,432
2. South-Eastern ...	Deptford	11	462	941,381
3. South-Western ...	Stockwell	8	340	582,591
4. Western	Fulham	6	224	690,138
5. North-Western ...	Hampstead ...	11	435	882,514
6. Northern	Winchmore Hill ...	36	480	—
			2383	4,211,056

The first five are in London. The Northern is for convalescents, and is four miles outside the northern boundary of the district. The position of these hospitals is shown on the map. The average length of the journey a patient has to be carried to reach the hospital nearest to his home is three and a half miles. During 1886–87 the number of beds in the eastern and western districts was found to be insufficient, and steps are now being taken to establish an additional hospital in the North-East of London, and to increase the number of beds in the Western Hospital to 400. These additions will give a total number of beds for fever and diphtheria of 2959, or one bed for every 1423 inhabitants. The total number of cases of fever and diphtheria admitted into the managers' hospitals from 1870 to the end of 1890 was 55,204. The accommodation for small-pox is the Floating Hospital at Long Reach, fifteen miles below London Bridge. It contains 350 beds for acute and severe cases on board the *Atlas* and the *Castalia*, the *Endymion* being used for administrative purposes, and 800 in the convalescent hospital at Gore Farm, four miles distant from the ships, giving a total of 1150 beds. The number of small-pox cases admitted into hospital since 1870 to 1890 is 56,979. To this number must be added 1028 cases other than small-pox, making a total of 58,007 admissions. The river service is exclusively used for small-pox cases, and consists of three wharves on the Thames in London for the embarkation of patients. The wharves, as shown on the map, are the "West" at Fulham, the "North" at Poplar, and the "South" at Rotherhithe. In each there is a floating pier in deep water, approached by a bridge, and a shed into which the ambulance carriage drives, with an examination room. As an example of the work, it may be stated that during the small-pox epidemic of 1884–85, 11,060 cases were removed from their homes to the Floating Hospital, 175 doubtful cases were sent from the wharves to the land hospitals, 38 cases were detained in London on account of fog, and 35 persons, not having small-pox at all, were vaccinated and taken home. The greatest number of patients taken down to the Floating Hospital in one day was 104, by the *Red Cross*, in three trips. At the close of the epidemic the Ambulance Committee were able to report the satisfaction they felt that so large a number of persons of both sexes and all ages, most of them in physical suffering, and many helpless from disease, had been carried in all weathers, throughout all seasons of the year, and to a great extent during the hours of darkness, without discomfort or detriment to the patients, and without mishap to any person whatever.

---

[1] 4·363 per 1000.

Sir Vincent Barrington, after urging the importance of preserving statistics of work done from an economical, as well as a sanitary point of view, presented statistical papers of fever and small-pox cases treated in Board hospitals. He commented upon the supposed prevalence of disease in 1887, and urged every publicity to be given to Board work, to get over the old prejudices of the working classes against sending patients to the isolated hospitals. He showed a chart demonstrating that the increased use by the public of the Board hospitals and the transport from 1879 to 1890, had been followed by steadily decreasing fever mortality in London. Now over half the cases of scarlet fever in all London are probably treated in Board hospitals. He referred to the improved sanitation of dwellings and the decreasing severity of the type of the disease as factors in the decreased mortality observed. He presented small-pox pedigrees in non-epidemic times, showwing in one case that 19 persons, in another 10 persons, were infected from a single case. Also that 20 cases of the 53 treated this year had been barren of infecting others as they were so rapidly removed to floating isolated hospitals. The deduction drawn was that the rapid system of removal of recent years by the combined land and river service of the Board had a sensible effect in checking a possible epidemic. He presented the forms for recording the evidence of the existence of vaccination cicatrices on the improved system adopted after conferences with Board medical officers and the Local Government Board, and advocated other sanitary bodies adopting the same system, thus facilitating the compilation of statistics, invaluable for the advance of science, and therefore for the treatment and check of small-pox, and the consideration of protection by vaccination.

Dr. Seaton, of London, Dr. Armstrong, of Newcastle, Dr. Dudfield, of London, Prof. Stokvis, of Amsterdam, and Dr. Hauser, of Madrid, also spoke on this subject.

Surgeon-General Beatson, M.D., of Eastbourne, read a paper on "Prevention of Disease in Growing Towns."

Prof. Stokvis and Dr. Dickson spoke on the subject.

Dr. Pistor, of Berlin, read a paper entitled "Ueber die Desinfection," of which the following is an abstract. Dr. Pistor dealt with the general rules and methods to be observed in the disinfection of infectious diseases. Such rules should be short, clear, and capable of being understood by everyone. Incineration and boiling for half an hour are, of course, very effectual disinfectants, but they are not always applicable. A 1 to 2 per cent. solution of caustic soda is a very useful disinfectant. Other methods are steaming, mechanical cleansing (such as rubbing, brushing, &c.), carbolic acid solution (2 to 5 per cent.), lime-water containing about 20 per cent. of caustic lime, and a 1 to 2 per cent. solution of calcined carbonate of soda. These methods and solutions are effective against all the poisons of infectious diseases. The head of the house or institution ought to be responsible for the disinfection under the direction of the doctor, and a record ought to be preserved of the mode of disinfection used.

Sir William Moore, K.C.I.E., Q.H.P., read a paper on "The Prevention of Fevers in India."

A discussion followed, in which Surgeon-General Cook of Bombay, the President, Surgeon-General Beatson, Dr. Leduc of Nantes, Dr. Payne of London, Surgeon-Major Poole of London, and Dr. W. Dickson, R.N., took part.

Dr. Prospero Sonsino, of Pisa, read a paper on "The Principal and most Efficacious Means of preventing the Spread of Entozoal Affections in Man."

Dr. Sandwith, of Cairo, and the President, made a few remarks.

Dr. F. M. Sandwith, of Cairo, read a paper on "Cholera in Egypt."

Dr. Stekoulis, of Constantinople, and Dr. Simpson, of Calcutta, took part in the discussion.

Dr. Curgenven, of Teddington, read a paper on "The Disinfection of Scarlet Fever and other Infective Disorders by Antiseptic Inunction."

Dr. W. Gemmell, of Glasgow, spoke.

Dr. Phineas S. Abraham, of London, read a paper entitled "On the Alleged Connection of Vaccination with Leprosy."

Mr. Milnes, of London, Dr. Cassidy, of Toronto, and Surgeon-Major Pringle spoke on this subject.

Dr. J. P. Williams Freeman, of Andover, read a paper entitled "Importance of more actively enforcing Ventilation: suggesting a Standard of Air Impurity as a Basis of Prosecutions." Dr. Freeman said that ventilation is of well-recognized importance; the causation of phthisis is a good example of it. Foul air is a cause of tuberculosis in three ways: *directly*, by supplying the bacillus to the lungs, and through the saliva to the intestinal canal; *indirectly*, by causing tuberculosis in cattle, and by so reducing the human body's vitality as to render it a suitable nidus. The bacteriologist leads us to expect that fresh air will be hostile to the virus; the demographist shows that the death-rate from phthisis increases from islands, coast districts, agricultural districts, small towns, to large towns; also in occupations, according to their exposure to the open air, from farmers and fishermen up to drapers and printers (see Dr. Ogle's table). The loss of health from want of ventilation is so familiar as to be little thought of, but the deaths from phthisis alone, fully preventable, must be enormous. The Public Health and Factories Acts provide for proper ventilation of buildings. Any standard that public opinion, lay and medical, may demand might be enforced. Beyond seeing to the cubic space in common lodging-houses, practically nothing is done, and the air of buildings is often "dangerous and injurious to health." An inspector should frequently "sample" the air of buildings, and if it exceed a certain limit of impurity the owner should be prosecuted, cubic space and means of ventilation being left for the architect; the limit to be when the air inside a building contains twice as much carbonic acid gas as the air outside at the same time. This would usually correspond to De Chaumont's "Rather close, organic matter becoming perceptible." Students of preventive medicine should demand this reform from the administrators of the law. Polluted air is as recognizable, preventable, and harmful as unsound food or bad water, and should be treated on the same lines.

Two other papers were taken as read, one by Dr. S. Lodge, Jun., of Bradford, entitled "On the Occurrence of the Broncho-pulmonary form of Anthrax amongst Rag-pickers in England, and Suggestions for its Prevention," and one by Dr. H. Rident, of Elbœuf-sur-Seine, entitled "Des Troubles du Côté des agents de la Respiration chez les Fileurs, et de leur Conséquences."

After a speech by the President, complimenting the Secretaries on their work, and a vote of thanks to the President, the meetings of the Section terminated.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, September 2.—Mr. Frederick DuCane-Godman, F.R.S., President, in the chair.—Mr. G. F. Scott-Elliot exhibited a series of various species of Diptera collected on *Ranunculaceæ*, *Papaveraceæ*, and *Cruciferæ*. He said that during the past summer he had studied about forty species of plants belonging to the orders named, and that they had all been visited by insects which were probably necessary for nectariferous flowers. The majority of the Diptera caught were not confined to one species or even genus, but, in view of the unmodified character of the flower in the orders named, this was only to be expected. Mr. Verrall observed that certain insects affected certain plants, but that the *Geraniaceæ* were seldom visited. The discussion was continued by Mr. McLachlan, Mr. Kirby, and others.—Mr. W. L. Distant exhibited a specimen of the orthopterous insect *Hemisaga hastata*, De Sauss., which, in the Transvaal, he observed to attack and feed on *Danais chrysippus*, a butterfly well known from its protective character and distasteful qualities to have a complete immunity from the usual Lepidopteral enemies. The *Hemisaga* lurked amongst the tops of tall flowering grasses, being consequently disguised by its protective resemblance to the same, and seized the *Danais* as it settled on the bloom. From close watching and observation, Mr. Distant could discover no other danger to the life of this well-known and highly protected butterfly.—Mr. T. R. Billups exhibited four species of Diptera, which he believed to be respectively *Oxycera terminata*, *Pipezella annulata*, *Clidogastra puncticeps*, and *Oxyphora arnicæ*, taken at Oxshott, Surrey, on July 11 last. He mentioned that all of them were recorded in Mr. Verrall's list only as "reputed British." He also exhibited a specimen of *Hypoderma bovis*, Deg., taken at Plumstead on July 29 last.—Dr. D. Sharp, F.R.S., exhibited several species of *Forficulidæ*, and called attention to the diverse conditions of the parts representing the wings in the apterous forms.—Mr. H. Goss exhibited living larvæ of *Scoria dealbata*, reared from ova. They were feeding on *Polygonum aviculare*, but not very freely; *Brachypodium sylvaticum* had been named as a food-plant for this species, but he did not find that the larvæ would eat this or any other grass.—The Rev. Dr. Walker exhibited, and read notes on, a collection of Lepidoptera, Hymenoptera, Coleoptera, Neuroptera, and Diptera, which he had recently made in Norway.

PARIS.

Academy of Sciences, September 7.—M. Duchartre in the chair.—Remarks on the influence that the aberration of light may exercise on spectroscopic observations of solar prominences, by M. Fizeau. Several observers have recently measured remarkably high velocities in solar prominences by the application of the Doppler-Fizeau principle. It is evident that if the matter of which the eruption consists be ejected in the neighbourhood of the ecliptic with a velocity equal to that of the earth in its orbit, the prominence will suffer an apparent displacement of 20″·445, in the same manner that a star is displaced by 20″·445 owing to the motion of the earth combined with the velocity of light. Aberration should therefore be taken into account in determining the positions and heights attained by the phenomena in question.—On the number of roots common to several simultaneous equations, by M. Émile Picard.—On the blending of separate chromatic sensations perceived by each of the two eyes, by M. A. Chauveau. If two colours are simultaneously and separately received on the corresponding points of the two retinas and transmitted respectively to the nervous centres, do they blend together at these centres and give rise to the sensation of the resultant colour? This is the question investigated by the author. And he finds that there is a real blending of the colour perceptions resulting from the independent excitation of each of the two retinas.—On the influence of the products of the culture of *naphyloccque doré* on the vaso-motor nervous system and on the formation of pus, by M. S. Arloing.—Observations of the asteroid discovered by Dr. Palisa on August 30, made at Toulouse Observatory, by M. E. Cosserat. Three observations for position were made on September 1 and one on September 2.—On the distribution in latitude of the solar phenomena observed at the Royal Observatory of the Roman College during the first half of this year, by M. P. Tacchini. Prominences have been most frequent in the southern solar hemisphere, as was also the case in 1889 and 1890, and the maximum of frequency in the zones ± 40°–50°. The spots and faculæ have preserved their preponderance north of the equator, with maxima of frequency in latitudes slightly lower than the prominences. All the phenomena have been rare near the solar equator.—Direct synthesis of primary alcohols, by M. Paul Henry.—On some attempts to reproduce acid rocks, by M. H. Le Chatelier.—On the quantity of starch contained in the tubercles of the radish, by M. P. Lesage.

PHYSICAL UNITS AND CONSTANTS.

Illustrations of the C.G.S. System of Units, with Tables of Physical Constants. By Prof. Everett, F.R.S. (London: Macmillan and Co., 1891.)

THIS may be taken to be the fourth edition of a work first published by the Physical Society in a somewhat different form. Those who know Dr. Everett need not be told that he has done everything that it is possible for an accurate, painstaking author to do, to bring each successive edition as near to perfection as possible. The value of the work to the physics investigator is exceedingly great, as everybody knows; but it is not so generally well known that it is an excellent class exercise book for students. There is much new matter in this edition, including determinations of viscosities, terrestrial magnetic elements, magnetic properties of iron and other substances, and heat measurements.

The labours of many men have given to the present generation this beautiful system of units, which has made physical calculation so easy, and which has pointed out in certain cases the directions in which new discoveries might be expected. And it only requires a short study of certain parts of this book to put any student in such possession of the system that he can use it with certainty and ease. Indeed, to become well acquainted with the scientific method of calculation has almost been made too easy for certain clever men of our acquaintance. It is far nobler to swim the Hellespont than to cross in a steamer. At the present time many clever men are possessed by a mania for crossing the Atlantic in boats of eighteen feet keel. It adds much more to one's credit to talk of all kinds of hybrid and home-made magnetic influences, than to use the simple idea of self-induction. In the same way it is unfair to say that certain practical engineers shirk the study of Dr. Everett's book; it is much better to put it that these gentlemen have too much originality to follow the easy path, and when in their practical applications of physical principles they adopt all sorts of ingenious units of their own manufacture to whose use there are limits in all sorts of ways, we can even feel sorrowful over their skilfulness, without attempt-to thwart their ambition.

The mechanical engineer is accustomed to the use of a curious unscientific want of system in his calculations. His unit of force is the weight of a pound in London. His velocity is in feet per second, perhaps, in the very same calculation as that in which his pressure is in pounds per square inch. It seems to be too late to change this. No engineer can venture to educate his pupils in the use of the C.G.S. system for mechanical engineering calculations. Mrs. Ali Baba measured her gold by the quart, and a mechanical engineer thinks and designs and talks with other engineers in the usual shop units; and we may as well think of altering our decimal system to a duodecimal one, as to talk of an alteration in the mechanical engineer's methods of calculation. It is a very great pity, but the difficulties in the way of reform seem to be insurmountable. The story of these difficulties is too long for the present notice. But in new applications of physics, in electrical engineering, for example, the use of the C.G.S. system is not only easy; it requires a large amount of ingenuity in any engineer to calculate in any other than in C.G.S. units, unless, indeed, he ignores all the experimental determinations already made for him and tabulated in the C.G.S. system. And yet such ingenuity has already been exercised, and laborious investigations have been carried out by some electrical engineers, with the result that certain parts of electrical engineering are getting to be even more unscientific in the units employed than any part of mechanical engineering. On behalf of the culprits we may say, however, that even Dr. Everett's book—their best guide—has not given them the precise information that it might have done. In the subject of heat, we can now ignore the steam-engine constructor; we can say to him, "Go on using your wretched pounds per square inch and your foot-pounds per minute, and we will go on using our dynes per square centimetre and our ergs per second because we are nearly independent of one another"; but we can make no such speech to the electrical engineer. We physicists have to say to him that we rely upon him to make new discoveries, to state to us new problems; and if he gives us information in vague units of his own, we cannot tabulate it for general use, and if he does not state to us his problem in the usual language, we are unable to understand him, and we can be of no mutual use to each other. But when he says to us that our language is cumbrous, that he has ideas to express for which we have no words, when he uses towards us, properly for once, that adjective "academic" which has been more misused than Shakespeare's word "occupy," the culprit and the judge change places.

We can blame him if he invents unsystematic units, but not until we have given him the language and units that are correct. And in some particulars the electric engineer has the right to blame us. For example, our definition of unit electric current is so stupid that a multiplier or divisor of π or 4π enters quite unnecessarily into all electro-magnetic calculation.

Concerning electro-magnets and the magnetic circuit of a dynamo machine or a transformer, the practical engineer has a simple and quite modern way of considering problems, not yet recognized in such orthodox books as this of Dr. Everett. *Magneto-motive* force and the magnetic *resistance* of a circuit are expressions which cannot be found in such a book, and it is not at all unusual for the orthodox physicist to treat the idea underlying the use of such expressions with profound contempt. The engineer and experimenter care less than nothing for "magnetic susceptibility" or for "intensity of magnetization," or for "free magnetism"; these are, to him, mementos of the time of twelve years ago, when the inventor made bricks in Egypt, and the very cleverest mathematical electricians were only distinguished from other inventors by the greater magnitude of their blunders. Dr. Hopkinson and Mr. Kapp and Mr. Bosanquet have given us simple ways of dealing with practical problems, and some of these are now known to every apprentice of an electric engineering factory; but we know of no mathematical treatise in which they are recognized. Is it too much to hope that Dr. Everett, in his next edition, will ignore the orthodox critics, and mention *ampere-hours*, and *ampere-turns*, and *Board of Trade units?* It would perhaps be going too far to expect him to speak of the drop of potential per ampere in 100 yards of "a cable of nine-seventeens," for he does not aim at displacing the electricians' pocket-books; but it is to be remembered that of all engineers the electrical engineer is the one who is most inclined to orthodoxy, who most leans upon the mathematician and physicist, who is most likely to use such a book as this; and if Dr. Everett can stretch a point in his favour, and devote, say, four pages to "electrical engineers' pocket-book" information, it will bind the electrical engineer to orthodoxy for ever. Why, for example, should Dr. Everett define the "impedance" of a circuit merely with reference to the circuit when conveying one particular kind of alternating current?

This book deserves much more than a short notice, and the time may perhaps come when one of our leaders will write a long critical article on the whole subject of units, pointing out the great differences in derivation of calorimetric units, for example, and the mere dynamical units employed in mechanics and electricity—an article which will teach the student that, although electric resistance has the same dimensions as a velocity, yet this is a very different thing from the statement that it *is* a velocity; that, in spite of Paris Congresses and Committees of the British Association, *sec-ohm* is a scientific name, and *quadrant* is not. But, over and above all this, the writer of the article must not be, as the present reviewer is, a poor specialist; he must criticize this book from the point of view of the general physicist. This book contains the results of all the best experimental work of more than a century. It is a book of mnemonics. A single line in the whole book recalls to us those magnificent memoirs of Dr. Andrews which revolutionized our ideas on liquids and gases, and yet that single line is quite enough to the physicist. It is dreadful and yet pleasing to think that all the work of a great man, or perhaps of a generation of great men, may be condensed into a single line of information in such a book as this. Would Dr. Andrews trouble himself very much over this fact if he were alive? or would he console himself with the thought that every physical fact discovered since 1869, and here recorded, was, to some extent, discovered through him, because he had made all physical workers his pupils? Would he need the consolation that Newton is not once mentioned, and that Sir William Thomson has less space devoted to him than the meanest of his pupils? Hundreds of years hence, the scientific world will be the better for the experimental work now going on, and it will have forgotten the name of almost every worker. Our determination of something is only right to four significant figures, and so it will never be quoted because a man of next century will have measured it with accuracy to five significant figures. How many of us can be sure that a single line of such a book as this, published a century hence, will be devoted to the record of any of his experimental results? Is there or is there not a satisfaction in knowing that, one thousand years hence, the names of even Faraday and Maxwell and Thomson will be as little known as ours. The age deserves a Homer, and a memory of thousands of years; and one book of the epic ought to be a list of all the men mentioned by Dr. Everett, saying what weapons each of them had brought for the common fight against the powers of darkness. But alas, the new Homer will probably not come into being for another three hundred years, and he will be a blind poet, and he will probably immortalize the wrong people.

JOHN PERRY.

OYSTERS.

Oysters and all about them. Being a Complete History of the Titular Subject, exhaustive on all points of necessary and curious information from the Earliest Writers to those of the Present Time, with numerous Additions, Facts, and Notes. By John R. Philpots (London and Leicester: Richardson and Co., 1891.)

The Oyster: a Popular Summary of a Scientific Study. By Prof. W. K. Brooks, of the Johns Hopkins University. (Baltimore: Johns Hopkins Press. London Agents: Messrs. Wesley, 1891.)

HISTORIANS of the oyster revel in ambitious titles. "The Oyster: Where, How, and When to Find, Breed, Cook, and Eat it" suggested a somewhat extensive field for the tiny octavo which Cruikshank illustrated, but yet greater anticipations are raised by the title of Mr. Philpots's contribution to the subject.

Unfortunately, this promise is not borne out; not from lack of labour on the writer's part, but from the want of that critical knowledge which can alone make a compilation of this nature valuable. Mr. Philpots has thrown together, with but little arrangement, into two volumes of 1300 pages, scraps from every conceivable source relating to the oyster, and this without any critical treatment whatever: all are oysters that come to his dredge. Since at least as much erroneous information is current about the oyster as about any other well-known animal, and since it appears to exert nearly the same deleterious influence as the horse on the truthfulness of those who deal in it, it will be readily understood that the 1300 pages abound with errors and contradictory statements, and form a most untrustworthy guide to the complicated subject of which they treat.

The melancholy side of the situation is that, had the compiler, evidently an enthusiast for his subject, devoted the time and labour expended on the collection of paragraphs from untrustworthy authorities, to qualifying himself for his task by obtaining a personal and practical acquaintance with the oyster in all its relations of life, he might have produced a less bulky work, but one of permanent value; as it is, the only passages which we have been able to identify as indicating that Mr. Philpots has seen an oyster or an oyster-bed, are to be found in his account of ten sorts of oysters sent to him by a London dealer, among which, by the way, the real native does not occur (pp. 332–36), and in chapter xix., containing a short account of the Poole fisheries.

To correct the errors of Mr. Philpots's authorities, and to indicate his omissions, would be to criticize, not one book, but all the readily accessible matter which has been written on oysters for the last half-century; accessible matter only, for even as a compiler Mr. Philpots has not the requisite qualifications for his task, being seemingly dependent for his information about foreign oysters upon the translations and abstracts which have appeared from time to time in the Report and Bulletin of the United States Fish Commission, and upon the Hand-books, &c., to the International Fisheries Exhibition. These, with Grenville Murray's "The Oyster, Where, How, When," &c. (1861 and 1863), Williams's "Silvershell; or the Adventures of an Oyster" (1856), and Eyton's "History of the Oyster" (1858), are the chief part of his stock-in-trade; to which may be added newspaper articles, reviews, extracts from popular natural histories, &c. Besides these "authorities," some fifty pages, largely taken from Gwyn Jeffreys's "Conchology," deal with Brachiopoda (!), Anomiadæ, Pectinidæ, and Ostreidæ; under the latter family there is an account of *Ostrea edulis*, but none of *Ostrea* (*Gryphæa*) *angulata* and *virginica*, although the book does not profess to be confined to the former species; and about 212 pages are occupied by reprints of Parliamentary papers of various sorts.

The only chapter in which we are at one with Mr. Philpots is that in which an appeal is made to the Government to take the "oyster question" seriously in hand, though even here we cannot but regret the tone in which he speaks of the Board of Trade. Unhappily, however, there is no denying the fact that the inspectors sent by the Board to report on oyster fisheries have often been unfit for their task, and have, sometimes at any rate, been freely fooled by interested parties, for want of a little practical acquaintance with their subject. This has been pointed out again and again, not only as regards oyster fisheries, but also in connection with other fishery questions; but it cannot be pointed out too often. A point to which Mr. Philpots should have drawn public attention is that, if the proposition to move the London drainage outfall to Foulness take effect, the best of the few remaining grounds for breeding the almost extinct "native" (*sensu stricto*) will in all probability be ruined.

A book of a different calibre is that of Prof. Brooks. It is avowedly merely an attempt to rouse the State of Maryland to take such measures with regard to the oyster-fisheries as can alone prevent their ruin, measures such as some other States have already taken with marked success. It is hardly necessary to say of Prof. Brooks that his little book is a clear and accurate summary of what is known about the American species, for few men can speak with more authority on the subject. We can only hope that the Legislature to which he appeals may be more far-sighted than our own. Had the restrictions which he advocates been laid on our English public beds fifty years ago, the rare "native" might be almost as cheap now as in those almost forgotten days when the market was not yet flooded with French and Dutch produce posing as the genuine article, and oyster grottos were a familiar feature of the streets.

THE DESTRUCTION OF MOSQUITOES.

Dragon-flies v. Mosquitoes. (New York: D. Appleton and Company, 1890.)

THE book before us consists of three prize essays written in response to a circular issued in 1889 to "The Working Entomologists of the Country," offering certain prizes for essays containing original investigations on methods for destroying the mosquito and the house-fly. The prizes were offered by Mr. R. H. Lamborn, whose position as Director of the Lake Superior and Mississippi Railway had caused him to spend a considerable time encamped in the swampy forests which surround the head of the great lake. Here he came into contact with mosquitoes of the most irritating kind, and here he made the interesting observations on their destruction by dragon-flies which stimulated him to offer the above-mentioned prizes. The lines laid down in the circular as to the direction which the investigations should follow have reference chiefly to the destruction of these insect pests by dragon-flies. The competitors were also required to examine which species of Odonata are best adapted for the purpose, to investigate their habits, and the possible methods of breeding them in large numbers. But although this line of inquiry is suggested, the practical object of the investigation is to determine whether it is possible to diminish or extinguish the noxious Diptera, and if so, by what means.

The essay which gained the first prize is by Mrs. C. B. Aaron, who gives a careful account of the habits and life-history of both the Diptera in question, and of the Odonata, and then considers the advisability and the means of exterminating the former. The gravest charge which is adduced against these Diptera, apart from the irritation they cause, is that they act as carriers of such parasites as Filaria, and possibly of some species of Tænia, whilst they undoubtedly serve to disseminate Bacteria associated with certain infectious diseases. In their favour it may, however, be said that they act as very efficient scavengers, especially during the larval period of their life-history; and it is a very open question whether the world would be much benefited by the total extinction of the two genera Culex and Musca. Without attempting to decide this point, Mrs. Aaron proceeds to consider the possibility and the cost of attempting their extermination.

The plan of pitting the dragon-fly against the gnat—a plan similar to that which Prof. Riley has brought to such a successful termination by encouraging the destruction of the orange scale, *Icerya purchasi*, by means of a small beetle, the *Vedalia cardinalis*, imported from Australia—is dismissed in a few words, for reasons which are considered at greater length in the following essays; but several mechanical means are suggested, the most promising and cheapest of which, in the case of the mosquito, is to spray with crude petroleum all collections of stagnant water which cannot be easily drained. The oil forms a thin film on the surface of the water, and effectually clogs the aperture of the breathing tubes as soon as the larvæ come to the surface, as they must do, for air.

The authors of the two remaining essays, Mr. Weeks and Mr. Beutenmuller, divide the second and third prizes. The former commences his essay with a valuable table, giving details of the time of appearance, of the comparative voracity, and of the habitat of sixteen species of dragon-fly found in the neighbourhood of New York. From these, three are selected—*Anax junius*, and *Æschna constricta* and *heros*—as the most likely to prove destroyers of mosquitoes. When, however, the life-histories of the opposed insects are compared, it becomes at once evident that we must not trust to the Odonata to rid us of the biting Culicidæ. The breeding and artificial rearing of dragon-flies present almost insuperable difficulties, for, when the larval stage is attained, each individual would have to be isolated, because they are apt to devour each other when confined in a limited space. Irrespective of the question of breeding, an insect which produces but one brood a year, and lives but a few days in the imago condition, has little chance of seriously affecting a race whose numerous annual generations succumb only to the severest weather. In its natural condition the dragon-fly does not correspond sufficiently closely with the mosquito, either in time or space, to give it any real chance of effecting the destruction of the latter; its breeding-places are also more restricted, as it requires a volume of water which is constant for some little time, whereas the mosquito, with its quicker metamorphosis, can make use of any temporary puddle.

The conclusion to be drawn from all three essays is, that if a serious attempt is to be made to combat these most annoying insects, the means to be adopted with most chance of success lie rather in the direction of draining swamps, raising fish, and encouraging water-fowl in the infested ponds, and, where it would not be injurious, using crude oil, than in any efforts to increase the supply of dragon-flies.

Mrs. Aaron and Mr. Beutenmuller have appended to their essays useful lists of papers on the subject of their work; and the latter has added a preliminary list of the Odonata in the State of New York, and a very useful catalogue of the "described transformations of the Odonata of the world." The book is illustrated with several plates, which depict stages in the life-history of the insects in question, and various mechanical devices for attracting mosquitoes, by means of lamps, to an oily grave; and for spraying with petroleum the water in which they breed.

A. E. S.

OUR BOOK SHELF.

Materials for a Flora of the Malayan Peninsula. No. 3. By George King, M.D., F.R.S., &c. Reprinted from the Journal of the Asiatic Society of Bengal, Vol. LX. Part 2.

DR. KING'S third contribution towards a flora of the Malayan Peninsula contains the *Malvales*, and comprises almost as large a proportion of new species as the two preceding parts, but no new genus. The Malvaceæ number twenty-four species belonging to eleven genera; the Sterculiaceæ, forty-eight species belonging to twelve genera; and the Tiliaceæ, fifty-eight species belonging to nine genera. Although 25 per cent. of the species are new, there are only three of the first natural order and five of the second; the rest belong to the Tiliaceæ, of which nearly half are new. Nine out of ten species of *Pentace* were previously undescribed, and only two others are known. There are seven additional species of the characteristic genus *Elæocarpus*, out of a total of twenty-three. This is the largest number of any one genus, though *Sterculia* comes next with twenty-two species. It will be perceived that the new species are almost exclusively trees. The flora of Malacca and Cochin-china is exceedingly rich in the arboreous element; the number of new species described by Dr. King in his various monographs and by Dr. Pierre in his "Flore Forestière de la Cochinchine" being something enormous.

W. B. H.

Zoological Wall Pictures. Three Diagrams, each 32 inches by 42 inches. (London: S.P.C.K.)

The Animals of the World, arranged according to their Geographical Distribution. Third Edition, Revised and Re-drawn. Size, 58 inches square. (London: Moffatt and Paige.)

THE first named depict (1) fishes, as represented by the cod, eel, and herring; (2) chelonians, as exemplified by the common water tortoise and the Greek land tortoise, together with drawings of parts of the chelonian skeleton; (3) insect pests, in the *personæ* of the Pine Bark and Colorado beetles, the larvæ of which are delineated. The diagrams are both bold and accurate, and good of their class.

The second named embodies an attempt to represent the distribution of the animals selected in latitudinal series. The plan, although a good one, is manifestly insufficient, inasmuch as by its means no provision can be made for overlap. However, for a bold wall diagram, the picture may be recommended. Its meaning is at once obvious; and a fact such as the occurrence of seals and whales at extreme latitudes, which at once arrests the attention, is sufficient in itself to arouse the spirit of inquiry in any active mind. In future editions the word "Some" might with advantage be substituted for the article "The" which heads the title.

Crozet's Voyage to Tasmania, New Zealand, the Ladrone Islands, and the Philippines, in the Years 1771–72. Translated by H. Ling Roth. Illustrated. (London: Truslove and Shirley, 1891.)

IN 1769 a Tahitian was brought to Europe by Bougainville as "a human curiosity." Afterwards he was sent to the Mauritius, the Governor of which was instructed to forward him to his destination. The task of restoring him to his native land was undertaken by Marion du Fresne, who was then a well-to-do resident in the Île de France; and thus originated the expedition the story of which is recorded in the present volume. The party started in two vessels, and Marion proposed, in the course of the voyage, to do much exploring work—a kind of enterprise for which he seems to have been well fitted, as he had been a distinguished officer of the French navy. Unhappily, some members of the expedition, including Marion himself, were massacred by the Maories. The voyage, however, was continued, and in 1783 an account of it was published which had been compiled and edited by the Abbé Rochon, the well-known traveller, from the log of M. Crozet, who, after Marion's death, commanded one of his two ships. It is this account which Mr. Ling Roth has translated. The work will be read with interest by students of the history of geographical discovery, and a good many of M. Crozet's statements about savage life have considerable value from the point of view of the ethnographer and the anthropologist. A preface, and a brief reference to the literature of New Zealand, are contributed by Mr. J. R. Boosé, Librarian of the Colonial Institute; and the volume contains, besides maps, very good illustrations of some works of Maori art.

Livingstone and the Exploration of Central Africa. By H. H. Johnston, C.B., F.R.G.S., &c. (London: G. Philip and Son, 1891.)

THIS volume ranks with the best of the series to which it belongs—"The World's Great Explorers and Explorations." Mr. Johnston realizes fully the splendour of Livingstone's achievements, and has succeeded admirably in bringing out their significance in the history of African exploration. He begins with two excellent general chapters dealing with the "natural history" and the "human history" of Central Africa; and afterwards he gives vivid accounts of all the various regions traversed by his hero. Thus the reader is enabled to form his own opinion as to the value of Livingstone's services. The strictly biographical part of the work is equally well done. All the world agrees that Livingstone was one of the noblest men who have ever devoted themselves to travel. This is felt strongly by Mr. Johnston, and he has been able to express his feeling effectively without extravagance and without any attempt at fine writing. The book will especially interest young readers, but may be studied with pleasure and profit by readers of any age. There are many good illustrations from photographs or drawings by the author, and seven maps by Mr. E. G. Ravenstein.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The National Home-Reading Union.

WHEN one remembers the difficulties with which one's own first efforts to study Nature were beset, it seems a pity that any youthful student should be ignorant of the existence of an organization which can do much towards making his path smooth.

The National Home-Reading Union endeavours to guide those who cannot obtain aural instruction into the safest and most attractive roads. Lists of books are drawn up; difficulties and discrepancies in systematic reading are, as far as possible, foreseen and removed in the pages of the magazine; questions are answered by those who conduct the courses. Last year and the year before, the courses on organic and inorganic Nature were in the charge of Mr. Francis Darwin, Dr. Hickson, and Dr. Kimmins. This year, geology is undertaken by Mr. Marr, and cryptogamic botany by Mr. Murray; and any persons who wish to work at these subjects may save themselves much labour and misplaced reading by writing to the Secretary of the Union, Surrey House, Victoria Embankment, for a prospectus. Mr. Murray tells me that it is often pitiful to see how mnch effort has been wasted by people who come to the British Museum to educate themselves, owing to the need of guidance to the right books with which to commence their studies.

I trust that this good work will commend itself to you as worthy of notice. ALEX. HILL.

Downing Lodge, September 17.

Notoryctes typhlops.

ALLOW me to protest against the misnomer "Marsupial Mole" applied to Dr. Stirling's marvellous mammal by Mr. Sclater, both in the *Times* and in NATURE. "Mole-like Marsupial" it may be, but the other phrase has quite a different meaning, and either shows a want of appreciation of important characters, or implies a theory which, however plausible, has not been proved. ALFRED NEWTON.

September 12.

"$W = Mg$."

I WISH that Prof. Greenhill would kindly explain to a bewildered reader of your paper the nature of his quarrel with "$W = Mg$," and with the writers of "theoretical" treatises who use this equation.

To those trained to regard quantity of matter as measured by its inertia, and who regard the "mass" of a body as the quantity of matter, so measured, which it contains, the equation $W = Mg$ has a pretty clear meaning.

A certain body "has a mass M," this being the measure of its inertia in terms of that of the mass-unit. This body is observed to have an acceleration g. We argue, from Newton's experimental laws, that there is a force acting on it; and we measure this force by a number which is the product of the two numbers, M (the measure of the mass of the body), and g (the measure of the acceleration observed).

If we observe a tight string attached to the body in question, and have every reason to believe that there is no other cause for the observed acceleration, we say that Mg measures the tension T of the string; or write "$T = Mg$." If the acceleration be due to the presence of the earth only, we say that the earth exerts a force [the "half" of the mutual stress] on the body, measured by Mg. This force we call the "weight of the body"; and the equation $W = Mg$ gives us the measure of the "weight" as deduced from the observation of rate of change of momentum produced by it.

If I felt sure that Prof. Greenhill considers M to be *still* merely a convenient abbreviation for $\frac{W}{g}$, I would say more on this matter; but I am in doubt as to what are the views of which he is so strong an opponent.

I see that he wishes to abolish "g" from works on hydrostatics. Why? I do not see how we can conveniently indicate the dependence [*cæteris paribus*] of hydrostatic pressure on the strength of the earth's gravitational field of force at any given place otherwise than by the introduction of g. But, as I have already implied, I am as yet in the dark as to the precise nature of the quarrel between Prof. Greenhill and the theorists.

Devonport, August 17. W. LARDEN.

[WE look to America for clear, unprejudiced ideas on the definitions of elementary dynamics, and Mr. Frederick Slate's letter from California is a valuable contribution, to which I hope Mr. Larden has directed his attention.

The quotations from certain elementary treatises which form Mr. Larden's letter are the statements it was my chief object to dispute; according to this school of writers, the Standard Pound Weight is not the lump of platinum preserved at the Exchequer, but rather it is the pressure on the bottom of the box in which it is kept.

When goods are sold in commerce by weight, they are weighed in scales, and the weight is the same wherever the weighing is carried out, whether at the equator, or the poles, or in the Moon, Sun, or Jupiter; so that the weight cannot be said to depend on the local value of g, the only effect of which is to slightly alter the infinitesimal strain of the balance.

Let Mr. Larden consult the recent Report of the Committee on Electrical Standards, to see how carefully the units must be defined to satisfy practical commercial requirements.—A. G. G.]

WHEN I was young, I never had the presumption to understand the use of "g" in questions connecting mass and weight, and I fear my boy takes after me.

He told me the other day that he understood how a falling body could have its velocity increased per second with a velocity of g, or 32 feet per second; and that he knew that m = stuff in a body, and w = its weight, but he could not see what the "blooming g" (I think that is what he called it) had to do with the matter.

I replied that no doubt, if we could only understand it, it had a beneficent use in the economy of nature.

TOMMY ATKINS, Senior.

Sleep Movements in Plants.

I READ the other day in a local paper that "Mr. Seemann, the naturalist of Kellett's Arctic Expedition," states that plants undergo sleep movements at regular intervals (presumably once in 24 hours) during the long period when the sun never sets. Has this been authenticated? I thought it was well known that a plant does not undergo periodic variations of the kind if it has never been subjected to the regular succession of light and darkness. Other instances are the daily periodicity of the strength of so-called "root-pressure" and of the rate of growth. But if the above observations are correct, not only have the sleep-movements become independent of the ordinary determining conditions in the individual, but they have become hereditary in the species. If the movements really possess the significance usually assigned to them (of checking excessive radiation) this would seem to negative the prevalent view that the state of panmixia alone suffices for the disappearance or degeneration of a structure or mechanism. A. G. TANSLEY.

September 19.

An Oviparous Species of Peripatus.

MR. DENDY's observation of the extrusion of incompletely developed eggs in Peripatus is not, as he appears to think, entirely new. Captain Hutton was the first to observe it, in *P. novæ-zealandiæ*, and I confirmed his observation for the same species in my monograph of the genus. No one knows whether the eggs so extruded undergo complete development. I am inclined to think that the process, which has only been observed in animals in captivity, is an abnormal one, and is caused by the alteration in the conditions of the animal's life. We know that the New Zealand species does bring forth fully-developed young.

I hope that Mr. Dendy will carry out his intention of fully investigating the development of the Australian species.

A. SEDGWICK.

Trinity College, Cambridge, September 18.

A Rare Phenomenon.

ON a visit to Dunecht, I was just leaving the Observatory about 11.18 G.M.T. on the 10th inst., when I saw a sharply-defined straight streak of light arching the sky from east to west. It was about 1° in width, and of uniform brightness from side to side, but more intense towards the western horizon, where it disappeared behind the trees at an altitude of some 4°. Eastward it extended across the constellation of Andromeda, near the girdle, quite beyond the convergence point of auroral rays, or fully 120° from the western horizon. This much I saw, but cannot say if the streak passed north or south of the Great Nebula.

Endeavouring to lay down its course, I perceived that it was rapidly fading, and at the same time drifting southwards at a rate of, perhaps, 1° in five minutes. At 11h. 21·0m. G.M.T. the western portion was considered to cross the celestial equator in R.A. 262½°, passing through a point in R.A. 310° and Decl. + 23° (1840·0). In the meantime the eastern portion had faded away. Although there was a bright aurora in the north-north-west, I did not think that the streak was auroral in character, but rather that it had been caused by the passage of a large meteorite. Next day, however, I stumbled on an account of a similar appearance seen, together with an aurora, by the Rev. Edmund Barrel, at Sutton at-Hone, in Kent, on March 30, 1717 (O.S.). In the Philosophical Transactions, vol. xxx., after describing an ordinary aurora, the account runs:—

"Near Eleven a Clock, there was (besides the *Northern* Brightness) a long Streak, not very broad, extended *East* and *West:* Which beginning in the *Serpent's-Head*, near *Hercules'-Club*, and covering *Arcturus*, proceeded near *Berinices Hair*, and so went over *Cor Leonis*, and thence to *Canicula*, [Procyon, for Sirius had already set] and ended a little beyond that Star. It shone very bright at first, but faded away in about Eight or Nine Minutes. If it had Motion (which I am not sure of) it was Southward. I waited for the next Fit of Brightness of the *Aurora;* and in about Seven Minutes, the *Eastern* Part of the Streak, viz. from the *Serpent's-Head* to near *Berinices Hair*, became visible again tho' dim, and was quite effaced in Four or Five Minutes more: And I did not yet perceive any Change of its Place."

The course described agrees fairly with the arc of a great circle 120° in length, joining Procyon and the head of Serpens.

Assuming the Dunecht arch to have been also part of a great circle, its highest point must have been 8° 50′ east of the meridian, at an altitude of 62° 24′ above the southern horizon. The Magnetic Survey of Profs. Rücker and Thorpe gives the point to which the dipping-needle is directed as 19° 49′ E.; altitude 71° 3′, for 1891·69.

A letter signed "Wigtownshire" in the *Scotsman* of September 14, dated September 12, says:—"There appeared here last night, between nine and ten, a very bright, luminous arch, reaching from south-west to north-east. It extended directly over the zenith from horizon to horizon, and formed a very interesting spectacle while it lasted, which was only about half an hour. It seemed to be of electric origin from its wavy motion, and was slightly tinged pink at the eastern point just above the horizon. . . ."

Assuming the correctness of the dates on which the arch was observed—and of the Dunecht date I am quite certain—it seems that this rare phenomenon was visible on two successive nights.

RALPH COPELAND.

Royal Observatory, Edinburgh, September 21.

LAST Friday, the 11th, my attention was called at 9 p.m. to a most remarkable appearance in the sky. It consisted of a luminous band stretching from the eastern horizon to the west, and passing a little to the south of the zenith. It was first seen here at 8.20, and began as a luminous ray coming up from the west, but when I first saw it, it had extended as described from west to east. It was like a straight tail of a large comet with its head below the horizon, or the track of the beam from a powerful electric search light. Its eastern end lay a little to the south of the Pleiades, which were just rising; and in the west it passed through Corona Borealis. The night was a brilliant starlight one, and small stars could be seen through the luminous band. It was seen in the Co. Kildare, 50 miles from here, and there it passed through the zenith also, which would show that it was at a great altitude. It gradually faded away, and was gone at 9.30. It would be of interest to know if it was observed in other parts of the country.

W. E. WILSON.

Daramona, Streete, Co. Westmeath, September 16.

SOME NOTES ON THE FRANKFORT INTERNATIONAL ELECTRICAL EXHIBITION.

I.

ON arriving in Frankfort one finds oneself in a lofty, palatial railway station, compared with which King's Cross looks mean and Victoria Station is a shanty. This new terminus at Frankfort is not, as with us, an hotel with trains whistling and shunting in the back premises; it is essentially a railway station, standing proudly alone at the western extremity of the town. And the practical Englishman is as much impressed by the completeness of its internal arrangements as by the anti-Ruskin lesson it teaches, that architectural skill when fitly applied to a railway station can produce as noble an edifice as when bestowed on a temple.

Leaving the railway station all is changed. We are on the outskirts of the town, amid unfinished houses, heaps of bricks, vacant plots strewn with rubbish, and the restless hammering of the house contractor. The Exhibition is close at hand, composed at first sight mainly of wooden hoardings, temporary structures, "restaurations," and *bier hallen:* it is the Chalk Farm fair again of our early youth, or Chicago in 1873, a month after the great fire. Presenting at the entrance a letter bearing the magic pass-words "Prüfungs Commission der Internationalen Electrotechnischen Ausstellung," we are ushered past the barrier with bows, and find ourselves surrounded on all sides by shows—Siemens and Halske's Miniature Theatre, admission 2½*d.*; Electrical Ballet, admission 1*s.*, 2*s.*, and 3*s.*; Diving Pavilion, seats 5*d.*, standing room 2½*d.*; Electrical Race Course, 2½*d.*; Siemens and Halske's Dancing Flames, 2½*d.*; and so on, all over the Exhibition grounds. Have we come all these miles, at an invitation conveyed to us through the English Foreign Office, merely to visit a collection of what are literally twopenny-halfpenny shows?

We try one of them, the Miniature Theatre, passing in by the stage door, through the courtesy of Messrs. Siemens' representative, and thus avoiding the crowd of people that flocks in at every one of the many afternoon and evening performances. In view of the audience are 48 handles, which work a large puppet show, but a puppet show without puppets, without music, without acting, without even a joke. Turning any one of 36 of these handles towards the left turns on a group of little white or red or blue incandescent lamps placed at the sides, at the top, and at the bottom of the little stage, but hidden by the scenery from the audience. Turning any one of these handles to the right also turns on the respective set of lamps, but now their brightness can be gradually diminished by revolving one of the remaining 12 handles, which gradually introduces resistance into the particular circuit. For example, either the red, or the white, or the blue lamps behind any side wing, top drop, or set piece, can be separately turned on, or all can be turned on and the brightness of the lamps of any one colour varied independently of the brightness of the remainder.

A bell tinkles, and the curtain rises, showing a pretty set scene of a Swiss village with mountains in the background. It is late in the afternoon. The attendant slowly revolves one of the resistance handles—the daylight wanes, the shadows grow long, the sun sets, and the snowy peaks of the mountains are ruddy with the Alpine glow. The effect is so lifelike and so beautiful that a spontaneous gasp of admiration is forced from the audience.

Then the stage grows gradually dark, lights are seen at the cottage windows, but the night is stormy, for the attendant now works the handles rapidly, as does the organist the stops when performing one of Bach's fugues: lightning plays on the hills, now a blinding flash lights up the road, the houses, and the waterfall; but the flashes grow less vivid, and one sees, or thinks one sees, the storm blowing away over the mountain tops. Presently the moon rises, the audience feel the quiet of the bright moonlight night, then the dawn, and finally the sunshine bathes the scene with light.

Since the opening of the Exhibition many theatrical managers, we were told, had ordered complete sets of this electric apparatus; and no wonder, for on it can be played a symphony in the music of colour.

We next went to see Messrs. Siemens and Halske's "dancing flames," the seats at this show being also well filled with a twopence-halfpenny paying audience. First, Koenig's manometric flames were described and shown in action; then Dr. Froelich's method of working them from a distance, the elastic membrane of the little gas-bag being pushed in and out, not directly by the air puffs, but by the motion of the ferrotyped iron disc of a telephone, the current through which was varied by speaking to a microphone. Next were shown some experiments, extremely interesting to the electrician, for illustrating graphically how self-induction, mutual induction, capacity, &c., affected the current produced by an alternate current dynamo.

We presume that the considerable number of people who, having paid for their entrance to the Electrical Exhibition, are willing to form group after group and pay an extra fivepence at the many performances that are given daily of these two shows by Messrs. Siemens and Halske, are not wholly ignorant of what they are paying to see. Probably, therefore, the continued attraction which such shows have for audiences drawn from the people is only another proof of the fact that science, and a love of science, have permeated to a much lower stratum of the nation in Germany than in England.

Numerous must be the Germans not much above the level of the sightseers at a village fair who have already listened to the explanation of Dr. Froelich's method for exhibiting these alternate current phenomena, and yet the method is novel to the majority of the English scientific visitors. For it was only some three months ago, when Prof. Perry showed his new steam-engine indicator to the Physical Society of London, that the President suggested how he thought it possible that that instrument might be converted into an oscillating telephone with a mirror on its iron disc, and used for projecting on a screen the current curve of an alternate current dynamo. But nobody at the meeting was apparently aware that Dr. Froelich had been employing a telephone with a mirror on its disc for this very object—such is the resistance to the spread of ideas introduced by difference of language.

The apparatus employed by Dr. Froelich is as follows:—A large telephone iron disc has a small piece of looking-glass stuck on it eccentrically, and at the back is a horse-shoe permanent magnet, the soft iron pole-pieces of which are wound with a coil carrying the current produced by an alternate current dynamo. The iron disc is therefore pulled more or less by the magnet, depending on the strength and direction of the current passing round its poles. A beam of light from an electric lamp is reflected from this mirror on to a screen, and as the alternating current flows round the magnet a vertical line of light is formed on the screen, the position of the spot of light on this line being at any moment a measure of the strength and direction of the current produced by the machine. At least, this will be the case if the natural period of vibration of the telephone plate be very small or very large compared with the periodic time of the current—a condition we presume Dr. Froelich has attended to.

To produce a motion of the spot of light at right angles to the former line, Dr. Froelich does not cause the telephone to be moved backwards and forwards with an oscillatory motion, by the rotation of the dynamo armature, as suggested at the Physical Society of London; but before the beam of light reaches the screen, he causes it to suffer a second reflection from one of a series of small plane vertical mirrors, arranged around the surface of a cylinder parallel to its axis. By suitable worm-gearing, the quick rotation of the dynamo causes a somewhat slow rotation of this cylinder, but quick enough to produce an apparently continuous horizontal beam of light along the screen if there be no current flowing—that is, if the mirror on the telephone plate be at rest. Hence, the combination of the vertical and horizontal motions of the beam produces a curve which shows the shape of the current-wave extending over some four or five periods.

The effect of adding self-induction or mutual induction or capacity to the circuit is instantly seen by the change in the shape of the current-curve on the screen, and the change of phase is also evident from the shifting of the whole series of waves sideways. The comparison between the current waves in the primary and secondary circuits of a transformer is also very prettily illustrated.

This lecture concluded with an exhibition of an apparatus that has been constructed for Dr. Froelich for the examination of compound sounds. On a shaft, turning at a uniform velocity, are eight little alternate current dynamos, and by pressing down a piano key, which closes the circuit of the particular dynamo, a current is sent round the soft iron pole-pieces of the horse-shoe permanent magnet at the back of a telephone disc. The number of pole-pieces and armature-coils on the respective dynamos are such that, on pressing down the keys in succession, the telephone emits the notes of an ordinary musical octave, and by pressing down two or more the compound sound is heard.

An Englishman finds it somewhat exasperating, if he desires to see the whole Exhibition, to have to be constantly taking out his purse to make small payments for entrance here and entrance there; but, as half the receipts for the shows go to the Exhibition authorities, they will be saved from the financial *fiasco* that attended the Edinburgh Exhibition of last year, for that Exhibition had to be finally declared bankrupt, even after all the money guaranteed by the promoters had been called up. Further, the shows are themselves illustrations of the application of electricity to industry and art: the mere bazaar element, that has been so prominent a feature at some of the Exhibitions held at Earl's Court, is practically non-existent at the Frankfort International Electrical Exhibition.

International, however, the Exhibition is but in name, the comparatively small exhibits of one or two English and American firms only serving as a reminder of the magnificent collections of electrical machinery and apparatus England and America could have contributed. As a display, however, of the part Germany is playing in the development of electrical industry, the Frankfort Exhibition is most interesting.

Two separate buildings are devoted respectively to electrical railway signalling and to telegraphic and telephonic exhibits. The Government have contributed an interesting collection of historical telegraphic apparatus, from which it may be seen that the signalling instruments have been going through the same sort of evolutionary changes in Germany as in England, with this difference, however, that our apparatus has reached a much later stage of development than theirs. The German telegraph wires have been well erected, although less attention than would satisfy an English telegraph engineer has been paid in obtaining that perfect symmetry in the hanging of the wires which is necessary to avoid contacts being produced between them as they are swayed backwards and forwards by the wind. The underground wiring is especially good, but the methods of testing and signalling are antiquated, and the routine of the Telegraph Department generally is fettered with red tape.

There is one detail, however, in connection with the German Post Office, that forces itself on the admiration of the foreigner. If you desire to send money, you hand in the sum at the post-office, with a postcard costing 2½*d*, which you address to your correspondent with details of the sum sent, and receive a receipt in exchange. But you need write no letter, send no postal order nor receipt, nor trouble your correspondent to go to the post-office; the postman delivers to your correspondent at his house or office your postcard, and in return for half of it hands him at once in cash the sum of money sent.

The display of telephonic apparatus at the Exhibition is large and complete, but owing to the activity of the commercial traveller of the day in keeping English engineers acquainted with practically all that is being done abroad, there is little that strikes the English telephone engineer as new. A new telephone exchange switch-board, constructed by Messrs. Mix and Genest, contains, however, a point of novelty, and a switch-board of this description has just been adopted at the Berlin Telephone Exchange.

The general arrangement of an exchange switch-board is as follows:—The wires from all the subscribers are brought to all the clerks at the exchange, so that it is possible for any clerk to connect any subscriber with any other, to enable the two subscribers to talk to one another. The calls, however, from certain subscribers only are received by any particular clerk; for example, of all the wires coming to clerk A, only those from, say, 1 to 100 are provided with drop shutters, so that if any subscriber from 1 to 100 rings up the exchange, one of the drop shutters in front of clerk A will fall, whereas if a subscriber from 200 to 300 rings up the exchange, it will be a drop shutter in front of clerk C that will fall. Each clerk, therefore, deals with the calls from a certain set of subscribers only, but this clerk may have to connect any one of this set of subscribers with any other of the same set or with any subscriber of any of the other sets; since, of course, any subscriber to the exchange has the right to be put in communication with any other.

Suppose, now, that clerk A receives a request from subscriber 85 to be put in communication with subscriber 560, the first thing to find out is whether the line of subscriber 560 is free, or whether it has been already connected with some other subscriber by one of the other clerks. This is usually ascertained by means of what is known as a "testing wire," which permeates all the switch-boards of all the clerks, and enables any clerk to see whether any line coming into the exchange is free or not. But in a large exchange the running of this testing wire throughout all the switch-boards necessitates the employment of many miles of wire, and it is to avoid this that Messrs. Mix and Genest have adopted the following new device:—

The ends of the plugs which the clerk presses into the various holes, or "spring jacks" as they are technically called, for the purpose of connecting one subscriber with another, are made electrically in two parts, the tip of the plug being insulated from the remainder by a piece of ebonite; a couple of cells are joined up at the exchange to each pair of plugs, in such a way that on inserting the tip of the second of a pair of plugs into a spring jack, an instantaneous current passes, deflecting the needle of a galvanoscope if the second line be free. For example, clerk A receives a call from subscriber 85 to connect him with subscriber 560: he inserts one of a pair of plugs into the spring jack 85, he then inserts the second plug into spring jack 560, and as the top of this second plug enters the spring jack there will be an instantaneous swing of clerk A's galvanoscope if line 560 be free, in which case the clerk pushes the plug home, and completes the connection between subscribers 85 and 560. If, however, the needle of the galvanoscope does not deflect, the clerk knows that line 560 is occupied, having been connected up by one of the other clerks, and instead of pushing home the plug he pulls it out, and tells subscriber 85 to wait, as line 560 is engaged.

Long-distance telephony is admirably illustrated by the opera at Munich being heard every evening with marvellous clearness at the Frankfort Exhibition, some 200 miles away.

The most striking feature of the Exhibition—indeed, the exhibit that has brought many a foreigner hundreds of miles to Frankfort—is the electrical transmission of power from Lauffen, over a distance of 109 miles. No measurements have yet been made by the jury of the exact amount of power that is received, or of the efficiency of the transmission; but as over 1000 sixteen-candle lamps are daily fed by the current, as well as an electro-motor pumping up water to form a large artificial waterfall, the actual power received must be something like 100 or 110 horse.

The plans had to be rapidly formed, for it was not until May 1 that it was definitely decided to carry out the experiment. The transformers have, on the one hand, been duplicated, from an anxious dread on the part of each firm of contractors that the other would not have finished their work in time; while, on the other hand, the insulators of the proper size are yet only partly ready, and many are defective from too hurried baking. Permission to carry the wires had to be obtained from the four Governments of Baden, Hesse, Würtemburg, and Prussia, and every step of construction had to be taken under the depressing influence of cavilling criticism. But in spite of all these difficulties, it has been conclusively proved that, by means of three overhead bare copper wires, each only 0·158 inch in thickness, supported on poles such as are used for ordinary telegraph lines, it is possible to deliver some 110 horse-power at a distance of nearly 110 miles from the water stream where the power is produced; and further, that this may be done without excessive loss by actually maintaining a potential difference of some 18,000 volts between each pair of wires.

The result is of international importance. The methods that have been employed (and which will be fully described) will probably not be copied in detail on a future occasion; there are doubtless faults which the cautious engineer can criticize; but the broad fact still stands out prominently, that, by an experiment as bold in conception as it has been successful in its realization, the Allgemeine Electricitäts Gesellschaft of Berlin, in conjunction with the Oerlikon Works of Zürich, have made the thoughtful realize that towns like Milan, which are within 30, 40, or 50 miles of vast water-power, may become the industrial centres of the future. It is, indeed, as if it had been shown that such towns stood on an inexhaustible field of smokeless, dustless coal.

(*To be continued.*)

SOME POINTS IN THE PHYSICS OF GOLF.

II.

IN my former paper (*Nature*, Aug. 28, 1890) the main conclusions were based to a great extent upon the results of mere eye observations, often of a very uncertain and puzzling kind. The data so obtained were unfortunately *not* those required for a direct investigation, so that my processes were necessarily of a tentative character. During and since the last College session I have been endeavouring to obtain some of the more important data in a direct manner. I am thus in a somewhat more favourable position than before but, as will soon appear, the new information I have obtained has complicated rather than simplified the singular problem of the flight of a golf-ball.

One point, however, which is both curious and important, has been clearly made out:—*hammering has no effect* (or, to speak more correctly, *only an inconsiderable effect*) *on the coefficient of restitution of a golf-ball.* This conclusion, which may have to be modified if the striking surface be not plane, had for some time appeared to me as almost certainly correct, and I have recently verified it by means of the Impact apparatus with which I have been working for some years. I procured from St. Andrews a number of balls of the same material and make, half of them only being hammered, the others plain. The results obtained from a hammered, and from an unhammered, ball did not differ much more from one another than did those of a number of successive impacts on one and the same ball. [In the *Badminton Library* volume on Golf, Mr. Hutchinson quotes a statement of mine which appears at first sight diametrically opposed to this experimental result; and thus puts me in the position *de nier ce qui est et d'expliquer ce qui n'est pas.* But he has omitted to mention that my statement was expressly based on the allegation that a hammered ball had been definitely found to acquire greater speed than an unhammered one. This seemed to me even at the time very doubtful, and I now know that it is incorrect.] Thus it is clear that the undoubtedly beneficial effects of hammering must be explained in some totally different way. There is another, and even more direct, mode of arriving at the same conclusion. To this I proceed, but unfortunately the new point of view introduces difficulties in comparison with which all that has hitherto been attempted is mere child's play. In short, it will be seen that the problem of a golf-ball's flight is one of very serious difficulty.

In my former article I took no account of the *rotation* of the ball, treating the problem in fact as a case of the motion of a particle in a medium resisting as the square of the speed. The solution I then gave was only approximate, and limited by the assumption that the cosine of the inclination of the path to the horizon might be treated as unity throughout. The illustrations and extensions given were founded on the same basis as was the solution of the simpler problem. Shortly after it was published I made, by the help of Bashforth's tables, a more exact determination. The data I thus arrived at were (in Bashforth's notation)

$$\lambda = 1\cdot9, \quad u_0 = 131 \text{ feet-seconds}, \quad \phi = 13^\circ\cdot5.$$

From these the tables give at once

Range of Carry... ... . = 542 feet
Maximum Height ... ... = 58 ,,
Horizontal Distance of Highest Point
from Tee ... ... = 350 ,,
Initial Speed ... ... = 480 feet-seconds
Terminal ,, ... = 80 ,,
Terminal Inclination ... ... = 38°·5.

As a contrast, take $\lambda = 1\cdot1$, so that $u_0 = 100$ feet-seconds. To obtain the observed range we must take $\phi = 23^\circ\cdot25$, which is considerably too great. The other numbers then become

Range of Carry... ... . = 543 feet
Maximum Height ... ... = 100 ,,
Horizontal Distance of Highest Point
from Tee ... ... = 350 ,,
Initial Speed ... ... = 393 feet-seconds
Terminal ,, ... = 80 ,,
Terminal Inclination ... ... = 54°·6

The first numbers are in remarkable accordance with the numerical details of really good drives which I obtained from Mr. Hodge; and, were there no other crucial test to be satisfied, the problem might have been regarded as solved to at least a first approximation. But I felt very suspicious of the sufficiency of such a solution; especially as it made no place (as it were) for the possibility of a path in part straight, or even occasionally concave upwards, which I have certainly seen in many of the very best drives. And my doubts were fully justified when I calculated from Bashforth's tables the time of flight under the above conditions. For they give 1·51s. for the first, and 2·13s. for the second, part of the path:—3·6 seconds in all; while the observed time of flight in a really good drive is *always* over 6 seconds, and sometimes quite as much as 7. This I have recently verified for myself with great care in the competition for the Victoria Jubilee Cup, where one of the unsuccessful players distinguished himself by really magnificent driving. The time of flight in the second of the above forms of path is about 4·8 seconds.

The initial speed in the first estimate seems to be excessive, as will appear from the experiments to be described below. This, of course, is one mode of explaining how the time of flight is so much underrated. But, if we keep to Bashforth's value of the coefficient of resistance, it is impossible to reduce the initial speed (while preserving the observed range) without increasing the angle of projection and, with it, the greatest height reached. The second set of numbers conclusively proves this. On the other hand if, with the view of reducing the initial speed and thus increasing the time of flight, we assume a smaller resistance, we may keep range, height, and initial angle, nearly as observed; but we shift the vertex of the path unduly towards the mid-range. The only way, it would therefore seem, of reconciling the results of calculation with the observed data, is to assume that for some reason the effects of gravity are at least partially counteracted. This, in still air, can only be a rotation due to undercutting.

During last winter I made a considerable number of experiments with the view of determining the initial speed by the help of a ballistic pendulum, but the results of these cannot be regarded as very satisfactory. My pendulum was a species of stiff but light lattice-girder constructed of thin, broadish, laths. This hung from hard steel knife-edges set well apart, and supported a mass of moist clay of about 100 lbs. The clay was plastered into a nearly cubical wooden frame, and swung just clear of the floor. The ball was driven into it from a distance of about six feet, and as near as possible to the centre of one face. The effective length of the corresponding simple pendulum was about 10 feet, and the utmost deflection obtained (measured on the floor) was about two inches. From these data I deduced an initial speed of about 300 feet per second only. But the experiments were never quite satisfactory, as the player (however skilful) could not free himself entirely from apprehension of the consequences of an ill-directed drive. In fact, several rather unpleasant accidents occurred during the trials, especially in the earlier stages; when the pendulum was mounted in a stone cellar, and without the hangings and the paddings which were employed in the later work. Although the clay was so stiff as to preserve its form under gravity, the ball (when it struck the face near the centre) always penetrated to a depth of more than one diameter, and splashed fragments of the clay to a considerable distance. These were usually replaced, and the surface levelled for a fresh experiment, as soon as the ball was dug out. The speed of 300 feet per second, thus measured, may be taken as an inferior limit to the initial speed in a really fine drive.

It thus appears that the resources of mere particle dynamics are quite insufficient for the adequate solution of the problem of long driving; though, of course, they fully meet all questions connected with mere approach shots; and that the rotation of the ball must play at least as essential a part in the grandest feature of the game, as it has long been known to do in those most distressing peculiarities called heeling, toeing, slicing, &c. But when this is once recognized, it is only the beginning of sorrows; for even the approximate treatment of the eddies produced by the rotation appears to be at present beyond our powers.

In order that the path of the ball may be (for a short time) approximately straight, still more if it is to be concave upwards, the downward acceleration due to gravity must be neutralized by the effects of a rotation due to *undercutting*. [Of course enormous speed could produce the approximately straight path, but not the concavity.] Hence the necessity for a tee, unless the turf be exceptionally soft, in order that the club may impinge on the lower part of the ball. Hence also one important use of hammering, viz. that the undercut ball may take as much angular velocity as possible:—the other being that the spin, so acquired, may tell as much as possible during the flight. The gist of the matter is thus seen to be:—For steady flight the ball must have rotation of some kind. The best mode, that of a rifle-ball, is of course unattainable. The others produce respectively heeling, toeing, dooking, and soaring. Of these the last, alone, is not necessarily disastrous; and it is therefore to be adopted.

I have not hitherto succeeded in my attempts to apply even approximate calculation to this altered set of conditions:—but it is easy to see, without calculation, that the longer the path of the ball retains nearly its initial inclination to the horizon (even if, in achieving this, it should have to expend part of its energy of translation along with that of rotation, and thus diminish the range) the longer will be the time of its flight during the carry.

And, as a practical deduction from these principles, it would appear that to secure the longest possible carry the ball should be struck so as to take on considerable spin:—so that the ideal driver should be in truth a Bulger, but with the important variation that its bulge should be of considerable curvature and in a *vertical*, not a horizontal plane. The height of the most prominent part of the face (above the horn) must of course be less than the radius of the ball How much less can be found only by trial. And, in addressing the ball, the player must stand directly opposite to it. Such clubs, however, could be profitably used only by really good players:—men who can hit with what part of the club they please. The reckless swipers of the present generation, who slash away anyhow, and (with ordinary clubs) manage occasionally to make a really "tall" drive, will probably smash the proposed form of club on the very first appearance of topping. As to those who propel the ball by "skittling" rather than driving, any change *must* be an improvement, so that they should welcome the proposed novelty. The matter is a very simple one. A few touches skilfully applied with a rough file, and the new system rises at once out of the old.

There is one other point on which opinion seems to be so unsettled that an allusion may be made to it here:—the effects of weather on the carry of a ball. Of course, other circumstances being the same, the only direct effect is on the coefficient of resistance. If this be taken as proportional (roughly) to the density of the air, it may vary, in this climate, to somewhere about ten per cent. of its average amount, by increase or by diminution. It has its greatest value, and the drive is accordingly shortest, on a dry cold winter day with an exceptionally high barometer. The longest drive will of course be when the air is as warm and moist as possible and the barometer very low.

P. G. TAIT.

HOOKER'S "ICONES PLANTARUM."

THE recent issue of the fourth part of vol. xx. of the entire work completes the volume, and closes the third series, with a total of two thousand plates. This useful, and now indispensable, publication was commenced by the late Sir William Hooker in 1837, and the first volume was dedicated to the late George Bentham, who is described in the dedication as an "ardent promoter, not less by his patronage than by his writings, of botany and horticulture." Sir William Hooker started the "Icones" to illustrate some of the numerous novelties in the collections which were pouring into his herbarium from various parts of the world, especially from the southern hemisphere, at that period. With a few exceptions by Harvey, Gardner, and others, the drawings and descriptions were by Hooker himself, and a volume, containing one hundred plates, appeared annually, or nearly so. The first series closed with the fourth volume in 1841. At this date the founder was already Director of Kew Gardens, and he continued the work to the tenth volume, which terminated the second series. Two or three of the later volumes of this series were illustrated by the then rising botanical artist, W. H. Fitch. In the tenth volume we find a dedication of the whole ten volumes to George Bentham, in much the same words as the first. This was in 1854. After an interval of thirteen years, the third series was commenced, under the editorship of Dr. J. D. (now Sir Joseph) Hooker; and G. Bentham, D. Oliver, and J. G. Baker were contributors. Mr. Bentham, we believe, financed the undertaking. This, the eleventh volume, was not completed until 1871; but it is a most interesting volume, illustrated by Fitch, and containing among other things many of the endemic plants of St. Helena. The second volume of this series, the twelfth of the whole, was also illustrated by Fitch, and is valuable for the figures of curious new genera founded by Bentham and Hooker when elaborating their "Genera Plantarum."

On the completion of this volume, in 1876, a difficulty arose, consequent on the retirement of the artist, though there was no actual interruption in the appearance of the parts. But it was impossible to replace an artist like Fitch. Indeed, the only alternative was to train a person to do the work. This was not so easily accomplished; there were failures, and so high a standard of excellence has not since been reached. Nevertheless, the present artist gives as good drawings as could be expected from dried, flat specimens, and the botanical details are usually as full as is necessary, if not all that could be desired.

Since Mr. Bentham's death, in 1884, the work has proceeded with greater rapidity, and is now appearing at the rate of a volume per year. It is now published at the expense of the Bentham Trustees,[1] and sold at about half the former price; and since his retirement Prof. D. Oliver has undertaken the editorship. Under such favourable auspices, together with the abundance of material in the Kew Herbarium, it is confidently hoped that the interesting character of the work will be fully maintained, and that the mechanical production of it will be improved, resulting in a larger sale. The later volumes contain a large number of Chinese novelties. One part of the last volume is devoted to the Stapeliæ of South Africa. The seventeenth volume is wholly devoted to new ferns; and the first volume of what it is intended to call the fourth series will consist entirely of orchids. Three parts of this have already appeared.

ON VAN DER WAALS'S TREATMENT OF LAPLACE'S PRESSURE IN THE VIRIAL EQUATION: A LETTER TO PROF. TAIT.

MY DEAR PROF. TAIT,—In Part IV. of your "Foundations of the Kinetic Theory of Gases,"[1] you take exception to the manner in which Van der Waals has introduced Laplace's intrinsic pressure K into the equation of virial. "I do not profess to be able fully to comprehend the arguments by which Van der Waals attempts to justify the mode in which he obtains the above equation. Their nature is somewhat as follows:—He repeats a good deal of Laplace's capillary work, in which the existence of a large, but unknown, internal molecular pressure is established, entirely from a statical point of view. He then gives reasons (which seem, on the whole, satisfactory from this point of view) for assuming that the magnitude of this force is as the square of the density of the aggregate of particles considered. But his justification of the introduction of the term a/v^2 into an account already closed, as it were, escapes me. He seems to treat the surface-skin of the group of particles as if it were an additional bounding-surface, exerting an additional and enormous pressure on the contents. Even were this justifiable, nothing could justify the multiplying of this term by $(v - \beta)$ instead of by v alone. But the whole procedure is erroneous. If one begins with the virial equation, one must keep strictly to the assumptions made in obtaining it, and consequently *everything* connected with molecular force, whether of attraction or of elastic resistance, must be extracted from the term $\Sigma(\mathrm{R}r)$."

With the last sentence all will agree; but it seemed to me when I first read Van der Waals's essay that his treatment of Laplace's pressure was satisfactory, and on reperusal it still appears to me to conform to the requirements above laid down. As the point is of importance, it may be well to examine it somewhat closely. The question is as to the effect in the virial equation of a mutual attraction between the parts of the fluid, whose range is small compared with the dimensions of bodies, but large in comparison with molecular distances.

The problem thus presented may be attacked in two ways. The first, to which I will recur, is that followed by Van der Waals; but the second is more immediately connected with that form of the equation which you had in view in the passage above quoted.

In the notation of Van der Waals (equation 8)

$$\tfrac{1}{2}\Sigma m\mathrm{V}^2 = \tfrac{1}{2}\Sigma f\rho - \tfrac{1}{2}\Sigma \mathrm{R}r\cos(\mathrm{R}, r),$$

where V denotes the velocity of a particle m, which is situated at a distance r from the origin, and is acted upon by a force R, while (R, r) denotes the angle between the directions of R and r. The intermediate term is to be omitted if R be the total force acting upon m. It represents the effect of such forces, f, as act mutually between two particles at distances from one another equal to ρ. In the summation the force between two particles is to be reckoned once only, and the forces accounted for in the second term are, of course, to be excluded in the third term.

In the present application we will suppose all the mutual forces accounted for in the second term, and that the only external forces operative are due to the pressure of the containing vessel. No one disputes that the effect of the external pressure is given by

$$-\tfrac{1}{2}\Sigma \mathrm{R}r\cos(\mathrm{R}, r) = \tfrac{3}{2}pv;$$

so that

$$\tfrac{1}{2}\Sigma m\mathrm{V}^2 = \tfrac{3}{2}pv + \tfrac{1}{2}\Sigma\rho\phi(\rho),$$

if with Laplace we represent by $\phi(\rho)$ the force between two particles at distance ρ. The last term is now easily reckoned upon Laplace's principles. For one particle in the interior we have

$$\tfrac{1}{2}\cdot 4\pi\int_0^\infty \phi(\rho)\rho^3 d\rho,$$

and this, as Laplace showed,[1] is equal to 3K. The second summation over the volume gives $3\mathrm{K}v$, but this must be halved. Otherwise each force would be reckoned twice. Hence

$$\begin{aligned}\tfrac{1}{2}\Sigma m\mathrm{V}^2 &= \tfrac{3}{2}pv + \tfrac{3}{2}\mathrm{K}v \\ &= \tfrac{3}{2}v(p + \mathrm{K}),\end{aligned}$$

showing that the effect of such forces as Laplace supposed to operate is represented by the addition to p, the pressure exerted by the walls of the vessel, of the intrinsic pressure K. In the above process the particles situated near the surface are legitimately neglected in comparison with those in the interior.

Van der Waals's own process starts from the original form of the virial equation—

$$\tfrac{1}{2}\Sigma m\mathrm{V}^2 = -\tfrac{1}{2}\Sigma \mathrm{R}r\cos(\mathrm{R}, r),$$

where R now refers to the *whole* force operative upon any particle; and it appears to me equally legitimate. For all particles in the interior of the fluid R vanishes in virtue of the symmetry, so that the reckoning is limited to a surface stratum whose thickness is equal to the range of the forces. Upon this stratum act normally both the pressure of the vessel and the attraction of the interior fluid. The integrated effect of the latter throughout the stratum is equal to the intrinsic pressure, and, on account of the thinness of the stratum, it enters into the equations in precisely the same way as the external pressure exerted by the vessel. The effect of Laplace's forces is thus represented by adding K to p, in accordance with the assertion of Van der Waals.

I am in hopes that, upon reconsideration, you will be able to admit that this conclusion is correct. Otherwise, I shall wish to hear more fully the nature of your objection, as the matter is of such importance that it ought not longer to remain in doubt.

Believe me yours very truly,

RAYLEIGH.

L'Abbaye de St. Jacut-de-la-Mer, September 7.

NOTES.

THE French Association for the Advancement of Science met at Marseilles on September 17, under the presidency of M. P. P. Dehérain, who chose as the subject of his address the part played by chemistry and physiology in agriculture. The meeting comes to an end to-day. There were general excursions on Sunday to Arles, and on Tuesday to Aix; and it is proposed that to-morrow, the 25th, there shall be a final excursion to the Mediterranean coast.

THE Congress of German Naturalists and Physicians was opened at Halle on Monday by Prof. His, of Leipzig. The meeting was attended by 1215 persons, including many distinguished foreign physicians and men of science and 280 ladies.

THE Helmholtz celebration, deferred from August 31, is now fixed for November 2. After the ceremony the delegates and others will dine together at the Hotel Kaiserhof.

---

[1] See also *Phil. Mag.*, October 1890, p. 292.

By the death of August von Pelzeln, which took place on the 2nd inst. at Ober-Döbling, near Vienna, Europe has lost one of her foremost ornithologists. He had been in failing health for some years, and had recently retired, after forty years' service, from his post of Custos of the Imperial Museum at Vienna, where he had charge of the collections of Mammalia and birds. Von Pelzeln will be always celebrated in the memory of zoologists by his important essays on the collections in the Vienna Museum, but his most enduring work will be found in the famous "Ornithologie Brasiliens," wherein he gave a detailed account of the collections made by the great traveller Natterer in the early part of the present century. Only last year he published in the *Annalen des k.k. naturhistorischen Hofmuseums*, an account of the formation of the collections of Mammalia and birds in the Imperial Cabinet, which is a very valuable historical record. The amiability of his character and his great knowledge of zoology had raised up for Von Pelzeln a host of friends in every country, and the news of his death will be received with wide-spread regret.

A Reuter telegram from New York announces the death of Prof. William Ferrel, the meteorologist.

The Royal Academy of Sciences at Lisbon send official notice of the decease of their Secretary, José Maria Latino Coelho, who died on the 29th ult. at Cintra, at the age of sixty-six. Besides his Secretaryship of the Académie Royale des Sciences, Prof. Coelho held the post of Director of the Mineralogical Section of the Museum at the École Polytechnique de Lisbonne.

The death of M. Wilken, the well-known Dutch ethnologist, has excited much regret in Holland, where his scientific work was greatly appreciated. He was forty-four years of age, and had spent some time as a Government official in the Dutch East Indies, where he had ample opportunities for carrying on his favourite studies.

Prof. K. Goebel has been appointed Professor of Botany in the University, and Director of the Botanic Garden at Munich, in the place of the late Carl v. Nägeli.

The Photographic Society of Great Britain announce the holding of an exhibition, which will be open from September 28 to November 12.

The most interesting part of the Royal Horticultural Society's exhibition on Tuesday was a series of the so-called carnivorous and insect-eating plants. It was hoped that the display of this series would tend to correct some very mistaken ideas which are said to be current on the subject. According to Mr. Weathers, the Assistant Secretary of the Royal Horticultural Society, some persons, relying on what they have heard, will assert that "these plants can easily dispose of a beefsteak or mutton chop if their digestive organs are in thorough repair."

The annual meeting of the Federated Institution of Mining Engineers was held on Tuesday at the Mason College, Birmingham, and was attended by about 120 members. Mr. T. W. Embleton, of Leeds, presided. In the report it was stated that the Council had not yet undertaken any special inquiry connected with the objects of the Institution, but their attention had been directed to the question of safe explosives for use in mines, the mechanical ventilation of mines, and other subjects. By the permission of the Durham Coal-owners' Association and the Durham Miners' Association, a report upon the fumes produced in mines by roburite, tonite, and gunpowder had been printed in the Transactions. The North of England Institution had appointed a committee to examine and report upon the so-called "flameless" explosives for use in mines. A paper sketching the geology of the Birmingham district was read by Prof. Lapworth. A paper was also submitted by Messrs. W. F. Clark and H. W. Hughes, in which the local method of working the thick coal was described to the visitors, and the peculiarities of the South Staffordshire coal-fields were described in technical detail. Mr. Arthur Sopwith supplied some similar information with reference to the North Staffordshire portion of the coal-field. These two papers were taken as read, and the discussion was deferred until the members of the Institution had visited the principal Staffordshire pits.

A Report for the year ending May 31 last, by Mr. G. J. Swanston, the Assistant Secretary of the Marine Department of the Board of Trade, upon the colour tests used in the examination of candidates for masters' and mates' certificates in the British mercantile marine has been issued as a Parliamentary paper. The number of persons who presented themselves for examination for masters' and mates' certificates of competency under Form "Examination 2" amounted to 4688, being an increase of 26 over the previous year, when 4662 were examined. In the past year 31 persons were rejected for their inability to distinguish colours, as compared with 23 rejected in the previous year. The number of persons examined in colours only under Form "Examination 2*a*" amounted to 601. Of these, 32 were rejected, being an increase of over 1·8 per cent. as compared with the previous year, when, out of 839 candidates examined, 29 were rejected. A few of those who failed to pass succeeded afterwards in satisfying the examiners. One man, who, on March 3, described a green card as drab, drab as green, pink glass as salmon and green, standard green as blue, bottle green as red, and neutral as green, passed a fortnight later, having apparently learned to distinguish the colours in the intervening period. The mode of conducting the colour-test examination described in the Report for the year 1887 is still in operation; but Mr. Swanston notes the fact that the whole subject of colour-vision and the best mode of conducting the examinations are now being investigated by a Committee appointed by the Royal Society.

On his return from Japan, sixteen years ago, Prof. Rein, the well-known authority on Japanese art and industry, planted in the Botanical Garden at Frankfort some specimens of the lacquer-tree (*Rhus vernicifera*), from which the Japanese obtain the juice employed in the production of their famous lacquer work. According to the *Times*, there are now at Frankfort thirty-four healthy specimens of the lacquer-tree, 30 feet high and 2 feet in girth a yard from the ground; and the young trees, which have sprung from the original tree's seed, are in a flourishing condition. It seems to be proved, therefore, that the lacquer-tree is capable of being cultivated in Europe, and it only remains to be seen whether the juice is affected by the changed conditions. The *Times* says that, to ascertain this, Prof. Rein has tapped the Frankfort trees, and has sent some of the juice to Japan, where it will be used by Japanese artists in lacquer work, who will report on its fitness for lacquering. In the meantime, some of the most eminent German chemists are analyzing samples of the juice taken from the trees at Frankfort, and samples of the juice sent from Japan; and should their reports and the reports from Japan be favourable, it is probable that the tree will be largely planted in public parks and other places in Germany. In course of time a skilled worker in lacquer would be brought over from Japan to teach a selected number of workmen the art of lacquering wood, and in this way it is hoped that a new art and craft may be introduced into Europe. Prof. Rein has been conferring with the authorities at Kew as to the results of his experiment.

The Hydrographic Department of the Admiralty has just published full details of the determinations of the latitudes and longitudes of six stations on the west coast of Africa—namely, Port Nolloth, Mossamedes, Benguela, St. Paul de Loanda, São Thomé, and Bonny. The observations were made in 1889 by Commander T. F. Pullen, R.N., and Mr. W. H. Finlay, under the direction of Dr. Gill, of the Cape Observatory. Whilst stationed at Bonny, Commander Pullen succumbed to malarial fever, and Dr. Gill has since taken charge of the reductions. The observations would not have been possible but for the courtesy of the officials of the Eastern and South African Telegraph Company, who placed their cables at the disposal of the observers.

Neptunia for July gives a description of the frigate *Scilla*, set apart by the Italian Government for the hydrographic exploration of the Mediterranean, and of its scientific fittings and instruments. By the end of September the *Scilla* was expected to be at work along the Italian possessions in the Red Sea, investigating the fauna and flora, and the temperature at different depths.

DR. A. ALCOCK, the Surgeon-Naturalist of the Marine Survey of India, is able to give a most favourable report of the work done in natural history on board the *Investigator* during the year ending March 1, 1891. The deep-sea researches made great progress. Not only has the work of collection been much more successful since the use of the reversible trawl and wire-rope, but the collections themselves are becoming better arranged; so that should it ever be decided to report upon them, group for group, in systematic detail, there will be abundance of material all sorted ready to the hand. Dr. Alcock is most anxious that such a report should at some time be undertaken; for apart from the Marine Survey of India nothing whatever, he thinks, is likely to be made known of the life of the depths of the Indian Seas, and of the physical and chemical characters of the deposits now being laid down on the bottom of those seas. Further, there are good reasons for supposing that an economic return would follow from the careful investigation of the little-known semi-bathybial fauna of Indian waters, and from a comparison between it and the semi-bathybial faunæ of the Mediterranean Sea on the one hand and the Japanese Seas on the other.

WE have received from Messrs. Philip and Son a new orrery for finding roughly the positions of the sun, moon, and planets for any hour of the year, and their times of rising, southing, and setting. In general appearance it resembles their well-known planisphere, but, in addition, it is provided with two index arms graduated in degrees of declination—one for the sun, and the other for the moon or planet. The operations are simple, but the instructions given scarcely do justice to the arrangements for carrying them out. An almanac is, of course, a necessary accompaniment to the orrery. We can recommend it to young students of astronomy.

A BOTANICAL Club for California has been instituted under the presidency of Dr. H. W. Harkness.

WE learn from the *Botanical Gazette* that Prof. J. M. Coulter has been spending the summer in studying the Cactaceæ of the borders of the United States and Mexico, under the direction of the Department of Agriculture at Washington; and that an expedition has been organized to investigate the flora of Mount Orizaba, Mexico, under the superintendence of Mr. H. E. Seaton.

A QUARTERLY Review of Geological Science in Italy will shortly appear at Rome, edited by Sigg. M. Cermenati and A. Tellini.

MR. CHARLES TODD, in his Report on the Rainfall in South Australia and the Northern Territory during 1890, says that without doubt "the feature" of the year was the extraordinary rainfall (especially in the first three months) over the eastern and north-eastern portions of the continent, which continued throughout the whole year, more or less, in New South Wales, and, whilst giving that colony the wettest year on record, caused some stations to register over 100 inches.

THE Pilot Chart of the North Atlantic Ocean for September states that the most important storm of the month was the hurricane that devastated the island of Martinique on the evening of the 18th, causing the loss of 378 lives. The storm seems to have been of comparatively small diameter, and it probably originated south-east of the island, which it passed directly over, on a west-north-west track towards San Domingo. It recurved over the eastern Bahamas, and thence moved north-east close to Bermuda; where at noon of the 27th the wind blew with hurricane force from north-north-west. The weather, the same as in this country, was unsettled and rainy over the North Atlantic generally, especially off the Atlantic coast of the United States, and a considerable amount of fog has been reported. A submarine earthquake was experienced at 10h. 30m. a.m. on August 23, in latitude 36° 44′ N., longitude 59° 47′ W., by the s.s. *Robert Harrowing*; Captain Hughson reports that a strange commotion of the sea increased until the decks were filled with water. At 1h. p.m. the sea suddenly fell calm.

COLORADO apparently intends to be well represented at the great Chicago Exhibition. Besides the mineral, agricultural, and educational exhibits, the flora and fauna of the State will be shown in great completeness. Already more than 1000 specimens of plants have been pressed; nearly 200 varieties of fruit have been duplicated in wax, and more than 2000 species of insects have been mounted.

RETURNS have been collected in Prussia, showing the extent to which buildings belonging to the State, or entitled to State subsidy for rebuilding or repair, were damaged by lightning from the year 1877 to 1886. The number of buildings to which the returns relate is 53,502. Of these, 264 were struck during the period in question, or about five for every 1000 buildings in ten years; and in 81 cases a fire resulted. The following facts, given originally in the *Reichsanzeiger*, are reproduced in the current number of the *Board of Trade Journal*:—Of the 264 buildings struck, 107 had towers, and in six cases only the tower escaped being struck. Of the total number of buildings struck, fifteen were fitted with conductors, and of these latter only one building escaped injury. In two cases the conductor was injured, and on one occasion the lightning passed from the conductor to an iron water pipe. In five cases they were so constructed as to be either dangerous or useless; in six cases they were not struck at all, being inadequate for the size of the building, from which it will be seen that conductors are a safeguard against lightning only when carefully constructed and repaired, and fitted in numbers according to the size of the building which it is intended to protect. The amount of injury wrought by lightning on the 53,502 houses was, on the whole, inconsiderable, being only 1,136,683 marks (£56,834), or 4306 marks (£215) for each casualty, or 21 marks (a guinea) per building in ten years, that is 2·1 marks (about 2*s.*) per building per annum.

SOME parts of Australia seem to be admirably suited for the growth of the olive. Mr. Principal Thompson, of Dookie, says in a recent report that 700 olive trees planted in that district are robust and healthy, and that they produce splendid oil. He strongly recommends the planting of the olive around vineyards and homesteads for shade and shelter, and to give a picturesque appearance to the rural home. Apart from the making of oil, he believes it would pay handsomely to grow olive berries to feed pigs alone. Last winter the pigs at Dookie (about 80 head) were allowed to eat up the fallen berries in the olive grove; they had no other food for upwards of two months, and throve amazingly, their skins having a peculiar shining appearance, characteristic of animals being well fed.

TOBACCO is being cultivated with much success in the German part of New Guinea, and is said to be better than the tobacco produced in Sumatra. It is expected that there will be a great increase in the amount grown during the coming year.

ACCORDING to M. d'Amagher, the Russian correspondent of the *Monde Economique*, a central Agricultural Institute is to be established in Russia. It will include several sections—agricultural, geological, meteorological, botanical, chemical, and technological; and branches will be formed in the provinces.

UNUSUALLY fine atmospheric effects were produced by the clear weather of the Mediterranean during the month of July. According to the *Mediterranean Naturalist*, the new monthly periodical issued in Malta, the phenomenon of irregular diffraction was especially shown by the raising of the line of sight to such an extent that objects at great distances, at other times completely concealed from view, were apparently raised so much above their true position as to be clearly discernible from the shores of Malta and Gozo. The cliffs of the coast-line, and the undulatory contour of the mountains of Sicily, were to be seen distinctly with the naked eye on July 11 and 12, while the outlines of Etna stood boldly out against the clear azure sky. Although more than 100 miles away, the form of the mountain was perfectly recognizable.

THE honey of the Malta bees has long been noted both for its purity and for its delicious flavour. A writer in the *Mediterranean Naturalist* says the flavour is largely due to the extensive crops of sulla (clover) that are annually raised throughout the islands, from which the bees derive the largest proportion of their material. It is estimated that to collect one pound of honey from clover, 62,000 heads of clover must be deprived of nectar, and 3,750,000 visits must be made by the bees.

SOME excellent directions for the collection, preparation, and preservation of birds' eggs and nests have been put together by Mr. C. Bendire, and published by the United States Nationa Museum. He begins his counsels by telling the would-be collector that unless he intends to make an especial study of oology, and has a higher aim than the mere desire to take and accumulate as large a number of specimens as possible regardless of their proper identification, he had better leave nests and eggs alone. The mere accumulation of specimens, Mr. Bendire points out, is the least important object of the true oologist. The principal aim of the collector should be to make careful observations on the habits, call-notes, song, the character of the food, mode and length of incubation, and the actions of the species generally from the beginning of the mating season to the time the young are able to leave the nest.

AT one of the meetings of the Wellington Philosophical Society in 1885, Sir Walter Buller, F.R.S., exhibited a series of the so-called wandering albatross, and expressed his belief that there were two species under the common name of *Diomedea exulans*, one of them being highly variable in plumage, and the other distinguished by its larger size and by the constancy of its white head and neck. But, although that was his conviction, he did not feel justified in setting up the new species and giving it a distinctive name until he could produce incontestable evidence of its existence. From a paper read by him before the same Society in February last, and published in the new volume of the Transactions of the New Zealand Institute, we learn that he had lately had an opportunity of examining sixteen beautiful specimens of both sexes and of all ages, and that as the result of his study of these specimens he had no hesitation in speaking of a new species. "It is undoubtedly," he says, "the noblest member of this group, both as to size and beauty, and I have therefore named it *Diomedea regia*." He exhibited before the Wellington Society a series of both species, and in the course of some remarks on them stated that they keep quite apart from one another on their breeding-grounds, and do not commingle "except when sailing and soaring over the mighty deep, where a community of interest and a common pursuit bring many members of this great family together."

IN the paper in which he deals with the species called by him *Diomedea regia*, Sir Walter Buller refers to a remarkable characteristic of the wandering albatross—a characteristic which has been carefully studied by Mr. Harris. At a certain time of the year, between February and June—Mr. Harris cannot exactly say when—the old birds leave their young and go to sea, and do not return until October, when they arrive in large numbers. During their absence the young birds never leave the breeding-ground. Immediately after the return of the old birds, each pair goes to its old nest, and, after a little fondling of the young one, turns it out, and prepares the nest for the next brood. The deserted young ones are in good condition, and very lively, frequently being seen off their nests exercising their wings; and, when the old birds come back, a young bird will often remain outside the nest and nibble at the head of the old one, until the feathers between the beak and the eye are removed, and the skin made quite sore. The young birds do not go far from land until the following year, when they accompany the old ones to sea. When the young are left in the nest at the close of the breeding-season, they are so immensely fat that Sir Walter Buller thinks they can subsist for months without food of any kind. Captain Fairchild has described to Sir Walter from personal observation the coming home of the wandering albatross, and the peremptory manner in which the young bird in possession is ordered to quit the nest, so as to make room for its successor.

THE habits of the kingfisher (*Halcyon vagans*) formed the subject of an interesting paper read some time ago by Mr. J. W. Hall before the Auckland Institute, and now printed in the Institute's Proceedings. He raised the question, Is it customary for the kingfisher to capture live birds? Last winter he saw one with a live white-eye in its mouth. The tree the kingfisher was perched upon was not many yards distant from him, and he distinctly saw the little wings flutter convulsively as the kingfisher was preparing to beat its prey against the branch. So it could not have been a dead bird casually picked up. Perhaps this, he said, was an application of the *lex talionis*, for, besides being mercilessly persecuted by the small boys with their catapults, the kingfisher was not infrequently captured by the common hawk. But sometimes the hawk does not come off best. One day at Parawai (Thames) a hawk sailed round the bend of a hill, followed (accidentally, he supposed) by a kingfisher. There at once arose a great outcry, and the hawk came again in sight, bearing the kingfisher in its talons. But, nothing daunted, the kingfisher with its pickaxe of a bill pegged away at the breast and abdomen of its captor to such good effect that the hawk was glad to liberate its prey, whereupon the kingfisher flew away apparently but little the worse for the encounter, and carrying with it, he need hardly say, the full sympathy of the onlookers. A friend of the author had seen a kingfisher dive under water to escape the pursuit of a hawk.

MR. J. CRAWFORD, State Geologist and Mineralogist of Nicaragua, visited in 1888 the Amerrique Indians, from whose ancestral name "America" may have been derived; and he has lately submitted to the Boston Society of Natural History some interesting notes about them. They occupy a hilly region in the gold-mining part of the district of La Libertad, Nicaragua, where there are "true fissures," each containing gold in sufficient quantities to give profits to the mine and mill owners now "operating" them. A few melted masses of gold, weighing from half an ounce to two ounces each, pierced with holes, and in form supposed to have been made and used as ornaments before the Spanish occupation, have been discovered in the district; and Mr. Crawford regards it as a fair inference that the Amerrique Indians who dwelt in that part of Nicaragua at the time of its discovery by Columbus, September 1502, picked up and occasionally mined, melted, and used gold for sacred or ornamental purposes. The Amerrique Indians are usually well formed, 6 feet 6 inches to 6 feet 8 inches tall; and they are active, and appear to be strong and healthy. Nevertheless, they are dying out rapidly. Probably not more than 275 or 300 of them are now living. They live in dim pathless forests, and their occupation is to find in the woods various species of trees (*Siphonia*, *Castilloa*, &c.) They deeply scarify these, collect the exuding emulsion, and separate the contained elastic ("India") rubber; and this "India" rubber they carry on their backs more than 100 miles to sell to merchants in Rama or at the mouth of Rio Matagalpa. They have cleared some patches of ground, and plant corn by making holes in the soil with pointed sticks. They believe that with allied tribes they had in very ancient times a mighty prophet or cacique, who appeared suddenly, full grown, in their territory, and that to him many tribes of Indians gave allegiance. The impalpable form of this ancient chief has been seen by very old Indians proudly walking and gesticulating on the top of Mesa Totumbla. He is buried in, or returns by day to, a deep cavern in this Mesa (a mass of gneiss); and he indicates, by gestures, that he will one day collect the Indians into a great army, and lead them in person to many victories. Mr. Crawford found his way into the cavern, and discovered in it three crania of Indians with other bones of their bodies. These were sent in 1889 to the Paris Exhibition, and were afterwards transferred to the U.S. National Museum. A few crude beads or ornaments, evidently earlier than the Spanish occupation of Nicaragua, were also found.

THE following are the arrangements for lectures during October at the Royal Victoria Hall:—October 6, Prof. T. Hudson Beare, the steam-engine, with experiments; October 13, Rev. Canon Browne, the invasion of England and Battle of Hastings, with illustrations from Bayeux tapestry; October 20, Mr. J. R. Green, flowers and their helpers; and October 27, Rev. E. Hill, the Channel Islands.

AT a meeting held last year by the students of the Kindergarten department of the New York College for the Training of Teachers, various papers were read on the principles and methods of the Kindergarten. These papers have now been issued as one of the educational monographs of the New York College. Miss A. Brooks, who contributes an introduction, says the School Board of New York City is considering plans for the introduction of the Kindergarten system into its schools; and a movement begun by the New York Kindergarten Association is destined, she thinks, "to accomplish great things for the neglected children of the city."

"EGYPTIAN SCIENCE," by N. E. Johnson, is the title of a work which will shortly be published by Messrs. Griffith, Farran, and Co.

THE Durham College of Science, Newcastle-upon-Tyne, has issued its Calendar for the session of 1891–92. This College represents the faculties of science and engineering in the University of Durham, and thus constitutes an important portion of the University of the north of England. But it does not restrict its work to science and engineering; it fulfils all the functions of a University College.

THE following works will shortly be published by Messrs. Crosby Lockwood and Son:—"The Mechanical Engineer's Pocket-book of Tables, Formulæ, Rules, and Data," a handy book of reference for daily use in engineering practice, by D. Kinnear Clark; "The Metallurgy of Argentiferous Lead," a practical treatise on the smelting of silver-lead ores, and the refining of lead bullion, including reports on various smelting establishments, and descriptions of modern furnaces and plants in Europe and America, by M. Eissler; "Engineering Chemistry," a practical treatise for the use of analytical chemists, engineers, iron masters, iron founders, students, and others, comprising methods of analysis and valuation of the principal materials used in engineering work, with numerous analyses, examples, and suggestions, by H. Joshua Phillips; "A Handbook of Brewing," a practical treatise for the use of brewers and their pupils, by Herbert Edwards Wright; "Condensed Machines," a selection of formulæ, rules, tables, and data, for the use of engineering students, science classes, &c., in accordance with the requirements of the Science and Art Department, by W. G. Crawford Hughes; "Milling," a treatise on machines, appliances, and processes employed in the shaping of metals by rotary cutters, including information on making and grinding the cutters, by Paul N. Hasluck, with upwards of 300 engravings; "Star Groups," a student's guide to the constellations, by J. Ellard Gore, with thirty maps; "Lessons in Commerce," by Prof. R. Gambaro, of the Royal High Commercial School of Genoa, edited and revised by James Gault, Professor of Commerce and Commercial Law in King's College, London.

AMONG the books announced by Messrs. George Philip and Son are the following:—"Delagoa Bay: its Natives and Natural History," by Rose Monteiro, with 20 original illustrations, after the author's sketches and from the natural objects, by A. B. and E. C. Woodward; "Paraguay: its History, Commerce, and Resources," by Dr. E. Bourgade, with 13 illustrations and a large coloured map; "Makers of Modern Thought," by D. Nasmith, Q.C.; "The Teacher's Hand-book of Slöjd," as practised and taught at Nääs, by Otto Salomon, Director of the Nääs Seminarium, with over 130 illustrations; "Hughes's Class-book of Modern Geography," an entirely new and completely revised edition, much enlarged by J. Francon Williams; "Geography of the British Colonies and Foreign Possessions," by the Rev. J. P. Faunthorpe, new and revised edition; "Systematic Atlas," for higher school and general use, a series of physical and political maps of all the countries of the world, with diagrams and illustrations of astronomical and physical geography, specially drawn by E. G. Ravenstein; "The Handy Volume Atlas of Astronomy," a series of 72 plates, with notes and index, by Sir Robert Stawell Ball, F.R.S.; "The Handy Volume Atlas of London," a series of 64 maps, with notes, compendium, directory, and complete index; "Atlas of Modern Geography," new and enlarged edition.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Mr. G. H. Sasse and Mrs. Gregorey; two Sykes's Monkeys (*Cercopithecus albigularis*) from East Africa, presented by Mr. F. Pardage; one Mozambique Monkey (*Cercopithecus rufo viridis*), one Garnett's Galago (*Galago garnetti*) from East Africa, one Blotched Genet (*Genetta tigrina*), one Ostrich (*Struthio camelus*) from East Central Africa, presented by Mr. Freith Anstruther; one Coypu (*Myopotamus coypus*) from South America, presented by Mr. Spencer H. Curtis; one Golden Eagle (*Aquila chrysaëtus*), European, presented by Mr. Herbert Bray; one —— Sand Grouse (*Pterocles* ——) from South Africa, presented by Mr. Max Michaelis; two Trocary Pigeons (*Columba trocary*) from Madeira, received from Dr. F. J. Hicks; one —— Elaps (*Elaps* ——) from Australia, presented by Mr. E. H. Meek;

one Rhomb-amarked Snake (*Psammophis rhombeatus*), four Crossed Snakes (*Psammophis crucifer*), one Hygian Snake (*Elaps hygiæ*), two —— Snakes (*Dasypeltis scabra*) from South Africa, presented by Messrs. Herbert Melville and Claude Beddington; one Smooth Snake (*Coronella lævis*), two Common Snakes (*Tropidonotus natrix*) from Oxfordshire, presented by Mr. A. W. S. Fisher; one Otter (*Lutra vulgaris*) from South Wales, received in exchange; two White-tailed Sea Eagles (*Haliaëtus albicillay's*) from Norway, three Indian Python (*Python molurus*) from India, deposited; one Macaque Monkey (*Macacus cynomolgus*) from India, one Pardine Genet (*Genetta pardina*) from West Africa, purchased; one Vinaceous Turtle Dove (*Turtur vinaceus*), bred in the Menagerie.

OUR ASTRONOMICAL COLUMN.

LIGHTNING SPECTRA.—Mr. W. E. Wood, of Washington, has continued his observations of lightning spectra for the purpose of determining the origin of some of the lines previously recorded by him (NATURE, vol. xlii. p. 377). The result is that he is now able to say, in the *Sidereal Messenger* for August:—"Lightning spectra present but the characteristic lines of oxygen, hydrogen, nitrogen, and carbonic acid, and—what was puzzling to me—the line of the vapour of sodium. The absorption bands which I find in lightning spectra I think might be produced by the moisture in the air, a large quantity being present during thunderstorms." It is suggested that the sodium line owes its presence to the existence of meteoritic *débris* in the atmosphere.

A NEW ASTEROID.—The 315th asteroid was discovered by Charlois on September 1.

THE INTERNATIONAL GEOLOGICAL CONGRESS: WASHINGTON MEETING.

THE fifth meeting of the International Geological Congress, being the first ever held in America, was held at the Columbian University, Washington, from August 26 to September 1, with an attendance of sixty or seventy foreigners, from Austria-Hungary, Canada, Chili, France, Germany, Great Britain, Mexico, Peru, Roumania, Russia, Sweden, and Switzerland, and about two hundred members from the United States. The papers and discussions were generally in English, though French and German were to some extent spoken. French has been the language of all the previous Congresses.

Profs. James Hall and James D. Dana were elected Honorary Presidents, and J. S. Newbery Acting President. Owing to the absence of the latter, the chair was filled in turn by several of the Vice-Presidents.

FIRST DAY.—After the election of officers, as nominated by the bureau, Prof. Joseph Le Conte, as senior Vice-President, took the chair, and delivered the opening address, in which he said that the idea of an International Congress was born in America in 1876. Previous meetings have been held at Paris in 1878, Bologna in 1881, Berlin in 1885, and London in 1888. He briefly stated the purposes of this Congress, which were afterwards carried out—namely, to discuss classification of the Pleistocene rocks, of correlation, and of map notation. He compared the maps of Europe and America, showing the complexity of the former and the simplicity of the latter. He then considered some points in American geology:—(1) The general continuity of the record. (2) The prevalence of extensive faults, ranging from 100 to 2000 feet, and extending over great distances. (3) Peculiarities of mountain structure. Prof. Gilbert has discovered a new type of mountains formed by uptilted strata. The Sierra Nevada is an illustration. (4) Extensive lava floods, covering areas from 10,000 to 100,000 square miles in extent, and from 2000 to 4000 feet deep. No such floods are found elsewhere. Those of India are the nearest approximation; but in Europe the lava beds are small and much cut up. (5) The great continental movement, commencing in the later Tertiary, and terminating in the beginning of the Quaternary, which has caused changes of level amounting to 2500 or 3000 feet on both sides of the continent. (6) The ice-sheet of the glacial epoch was first and most completely demonstrated in America.

Other addresses were delivered by Mr. Hubbard, Chairman of the Local Committee; Mr. Noble, Secretary of the Interior, who has official control and supervision of the Geological Survey of the United States; Prof. Hughes of England, Prof. Gaudry of France, and Major Powell, Chief of the Geological Survey.

SECOND DAY.—The entire day was occupied by a discussion on classification of the glacial Pleistocene deposits. Prof. T. C. Chamberlin opened the discussion by stating that classification might be made on three grounds: (1) structural; (2) chronological; (3) genetic. The first was very easy, being an obvious division into assorted and unassorted drift. The second was extremely difficult, and could not be accurately made till after a full determination of the third. He accordingly proposed the following general classes: (1) formations produced by the direct action of Pleistocene glaciers; (2) formations produced by the combined action of Pleistocene glaciers and accompanying glacial drainage; (3) formations produced by glacial waters after their issuance from Pleistocene glaciers; (4) formations produced by floating ice derived from Pleistocene glaciers; (5) formations produced by shore ice and ice floes due to low Pleistocene temperature, but independent of glacier action; (6) formations produced by winds acting on Pleistocene glacial and glacio-fluvial deposits under the peculiar conditions of glaciation.

This paper was discussed very thoroughly. Prof. T. McK. Hughes pointed out that the classification suggested by Prof. Chamberlin was purely genetic. He then explained the abundance of striated boulders in one part of the glacial deposits and their absence in another. If the supply of material (that is, of rock bosses above the ice) ceases at any point, then all the boulders will gradually sink through the ice and become glaciated at the bottom. Prof. Hughes also thought that two distinct types of ridges formed of glacial material were confused under the names—kames, osars, and eskar. He also explained the "pitted plains" as due to an unusual interruption between the hills or ridges of eskar character. He expressed his opinion that the glacial period was a continuous one, in England at least, except for slight changes due to unimportant oscillations.

Mr. McGee mentioned the importance of land forms in interpreting geological processes. Any primary geological classification must be genetic. He discussed in detail the following scheme of classification of Pleistocene deposits:—

Classification of Pleistocene Formations and Land Forms.

A. Aqueous:
  1. Below base level.
    a. Marine.
    b. Estuarine.
    c. Lacustral.
  2. At base level.
    a. Littoral.
    b. Marsh.
    c. Alluvial (certain terraces, &c.).
  3. Above base level.
    a. Torrential.
    b. Talus (including playas).
B. Glacial:
  1. Direct (Chamberlin's Class I.).
  2. Indirect (Chamberlin's Classes II. to V., in part).
C. Aqueo-Glacial (Chamberlin's Classes II. to V., in part).
D. Eolic (Chamberlin's Class (?) VI.).
E. Volcanic:
  1. Direct.
    a. Lava sheets.
    b. Cinder cones.
    c. Tuffs, lapilli sheets, &c.
  2. Indirect.
    a. Ash beds.
    b. Lapilli sheets.

Prof. Chamberlin, in closing the discussion, said that there was great difficulty in applying a chronological classification, and that such a classification might even act as a barrier to observation and to the recognition of the truth. Chronological classification is the ultimate goal of glacial studies, but it is something for which we are not as yet prepared. Red, oxidized sub-soils are not developed in northern latitudes. Organic deposits between glacial layers are abundant in the West, but do not belong to a single horizon. Many facts of erosion and physical geology indicate that the Glacial epoch in America was widely differentiated and of long duration. How many distinct periods it embraced we do not as yet know.

Prof. Cope said an abundant tropical fauna is found in the "Equus beds," which, if they be of interglacial age, indicates at this time a very warm climate. This fauna is succeeded by a truly boreal fauna. In this is contained material for a chronological subdivision of Pleistocene deposits.

THIRD DAY.—The President announced as the subject for discussion, the correlation of geological formations.

Mr. Gilbert opened this discussion by presenting a general classification of methods of correlation.

Strata are locally classified by superposition in chronologic sequences. Geologic correlation is the chronology of beds not in visible sequence. For convenience in discussion, methods of correlation are classed in ten groups, of which six are physical and four biotic.

Physical Methods of Correlation.

(1) Through visible continuity. The outcrop of a bed is traced from point to point, and the different parts are thus correlated one with another.

(2) Strata are correlated on account of lithologic similarity. This method, once widely prevalent, is used where the distances are small.

(3) Correlation by the similarity of lithologic sequence has great and important use where the localities compared fall within the same geologic province, but is not safely used in passing from province to province.

(4) Physical breaks, or unconformities, have a limited use, especially in conjunction with other methods. The practice of employing them in the case of localities wide apart is viewed with suspicion.

(5) Deposits are also correlated with their simultaneous relations to some physical event—for example, a beach with the lake beds it encircles; a base level plane with a contiguous subaqueous deposit; and alluvial, littoral, and subaqueous deposits standing in proper topographic relation. In the Pleistocene, glacial deposits are widely correlated with reference to a climatic episode assumed to arise from some general cause.

(6) Deposits are correlated through comparison of changes they have experienced from geologic processes supposed to be continuous. Newer and older drift deposits in different regions are correlated according to the relative extent of weathering and erosion; induration and metamorphism afford presumptive evidence of age, but yield to evidence of other character. Metamorphism holds prominent place in the correlation of pre-Cambrian rocks where most methods are inapplicable.

These physical methods are qualified by the geographic distribution of geologic processes of change and of geologic climates.

Biotic Methods of Correlation.

(7) A newly-discovered fauna or flora is compared with a standard series of faunas and floras by means of the species it holds in common with them severally.

(8) It is also compared by means of representative forms, or through genera and families.

(7*a*) and (8*a*) These comparisons are strengthened if two or more faunas in sequence are found to be systematically related to the faunas of a standard series.

(9) Two faunas or floras otherwise related are compared in age through their relation to the present life of their localities. This method was applied by Lyell to Tertiary rocks.

(10) Faunas are correlated by means of their relation to climatic episodes taken in connection with station. For example, boreal shells found in latitudes below their present range are referred to glacial time.

In general the limitations to accurate correlation by biotic methods arise from the facts of geographic distribution. Correlations at short range are better than those at long range.

Biotic correlation by means of fossils of different kinds may have different value. In general, the value of a species for the purposes of correlation is inversely as its range in time, and directly as its range in space. The value of a biotic group depends (1) on the range of its species in time and space; (2) on the extent to which its representatives are preserved.

Prof. K. von Zittel spoke in reference to the biotic methods, and gave his opinion of the relative value of plants and animals for purposes of correlation. He regarded plants as relatively unimportant. Among animals, those which are marine, lacustrine, and land animals may be distinguished. Of these classes marine invertebrates are most valuable for purposes of correlation. The vertebrates change rapidly, but are frequently altogether wanting. For instance, no vertebrates occur in the Alpine beds corresponding in age to those which contain the mammalian fauna of the Paris basin. In certain lacustrine deposits invertebrates may be absent, and in such cases the vertebrate fauna is the surest guide.

Baron de Geer emphasized the importance of a numerical comparison between different species. The actual counting of individuals in a given formation is of great value.

Prof. Marsh expressed his agreement in general with the conclusions communicated by Prof. von Zittel, but would give special weight to vertebrate fossils. In the Mesozoic and Tertiary beds of the Rocky Mountains he had found that the vertebrates offer the surest guide for correlation. This is in part because invertebrates are either wanting or are lacustrine. Prof. Marsh in 1877 named a sequence of horizons after the most characteristic vertebrate genus in each which is confined exclusively to it. He presented an outline of such classification brought down to date, with a section to illustrate vertebrate life in America.

Mr. C. D. Walcott spoke of the value of plants for purposes of geologic correlation.

Prof. T. McK. Hughes spoke of the present and growing tendency towards a natural classification. The evidence is complex, and includes a considerable variety of diverse relations. He pointed out exceptions to the normal conclusions deduced from superposition, lithological character, and similarity of sequence. We must have a system of criteria so varied that if one or more fails others can be employed. All classes of evidence are useful, both positive, negative, and circumstantial.

Major J. W. Powell spoke of the necessity of specialization on the part of geologists engaged in the work of correlation. The evidence derived from physical and biotic facts might apparently disagree. But that a satisfactory result may be reached, these two classes of evidence must be brought into harmony. He cited an example from his own experience, of how an identification of synchronous formations might be made over a wide area through a union of physical and biotic methods.

Mr. W. J. McGee remarked that in the coastal plain of the United States physical correlation alone is employed. The bases accord with those outlined by Mr. Gilbert, with certain minor modifications and an important addition, as follows:—

For local discrimination and correlation	Visible continuity; Lithologic similarity; Similarity of sequence.
For correlation throughout the province... ...	Physical breaks viewed as indices of geography and topography.
For correlation with contiguous provinces ...	Relation to physical events, including continental movements, transportation of materials, land sculpture, &c.
For general correlation...	Homogeny or identity of origin.

By correlation upon these bases the physical history of a considerable fraction of the continent may be so definitely ascertained as to permit fairly accurate mapping of the geography, and even the topography of each episode in continent growth. After these episodes are clearly defined, and the fossils found in the formations are studied, it will be possible definitely to ascertain the geographic distribution of organisms during each episode; then palæontology may be placed on a new and higher plane.

Prof. W. M. Davis showed that it was possible to decipher geological history not only through the records of deposition, but also by processes of degradation. As an example of this method he explained a topographical section from the city of New York westward. In this we have evidence of the existence of an ancient *peneplain*, or base-level lowland of Cretaceous age. This surface was subsequently elevated (more toward the west than toward the east) at the end of Cretaceous, or at the beginning of Tertiary time. It has since been dissected by the excavation of more recent valleys. The Hudson Valley lowland was cited as an example of this recent dissection.

Prof. E. W. Claypole considered that the different methods of geologic correlation differed very greatly in their value. It is improbable that the plant or mammalian record will ever equal in its perfection that of the marine invertebrate fauna. The marine fauna is to the geologist what a primary triangulation is to the geodesist. It marks out the main divisions, which are subsequently further subdivided through the aid of other fossils, such as plants and vertebrates.

Prof. C. R. Van Hise spoke of the methods of correlation employed for pre-Cambrian rocks, which occur in widely separated areas and are devoid of fossils. Physical data only are available for correlating these formations. Experience has shown that, among all physical methods, unconformity is by far the most important. Other physical criteria, such as the degree of induration, metamorphism, and relation to eruptives, are valuable for the subdivision of single areas, but cannot be safely used in identifying synchronous formations in widely-separated areas. The idea that lithological character is any direct proof of geological age has retarded the scientific subdivision of pre-Cambrian rocks. The researches of Pumpelly and others in the eastern United States have demonstrated that Silurian, Devonian, and even Carboniferous deposits might become, under certain physical conditions, as highly crystalline as much more ancient rocks of the West. For this reason it has been found necessary to abandon such terms as *Huronian* and *Keweenawan*. Evidences of life are not lacking in pre-Cambrian rocks, and it is to be hoped that the palæontologist will succeed in differentiating several separate formations below the Cambrian, as the Cambrian itself was differentiated from the base of the Silurian.

FOURTH DAY.—Prof. E. W. Hilgard laid stress upon the importance of the abundance or scarcity of species in the correlation of strata. He thinks some quantitative estimation of the species should be made. He is of the opinion, also, that, as compared with marine fauna, plants have but little value for purposes of correlation owing to their local distribution, their accidental proximity to water, transportation, and preservation. Plants can be so used only after large areas are worked over.

Prof. Lester F. Ward continued the discussion. He developed two of the more general principles of correlation by means of fossil plants, as follows :—

(1) That the great types of vegetation are characteristic of the great epochs in geology.

This principle is applicable in comparing deposits of widely different age when the stratigraphy is indecisive. For example, even a small fragment of a Carboniferous plant proves conclusively that the rocks in which it occurs are palæozoic, or a single dicotyledonous leaf proves that they must be as late as the Cretaceous.

(2) That for deposits not thus widely different in age, as, for example, within the same geologic system or series, ample material is necessary to fix their position by means of fossil plants.

Neglecting this principle has led to the greater part of the mistakes of palæobotanists, and has done most to bring palæobotany into disrepute. Geologists have expected too much of them, and they, in turn, have done violence to the truth in attempting to satisfy extravagant demands. On the other hand, where the material is ample, fossil plants have often corrected the mistakes of stratigraphical geologists, and solved problems concerning geologic age, which seemed impossible of settlement by any other class of evidence.

Prof. Henry S. Williams laid stress upon the relations of species to the conditions of deposition. The abundance of a species varies with environment, and a study of correlation should embrace a study of these conditions. Sandstones deposited near shore may have a fauna different from that of a limestone deposited off shore at the same time, and a change of fauna may be induced by a change of the conditions of deposition. The age of beds should be determined by comparing species of the same genera rather than by comparing those of different genera. There are centres of abundance which exhibit great variability in their characters; outside of these centres the species exhibit varieties which may be called extralimital, and which are not typical though they have often been published as types.

Prof. Charles Barrois said that there was no general basis, either biologic or lithologic, for the correlation of the pre-Cambrian rocks of Europe with those of North America ; even the terms applied to these rocks were liable to be misunderstood. Certainly the divisions used in France cannot be correlated with those now used in the United States. General correlation cannot, as yet, be based upon nonconformities ; autopsy is the only basis upon which a comparison can be instituted. He pointed out certain parallelisms between the histories of the crystalline schists of America, as illustrated by Mr. Pumpelly, and the gneissic rocks of Brest, where the Cambrian slates are altered to gneisses of Archæan aspect, while the alternating fossiliferous quartzites are changed to crystalline quartz. Geologists must see the beds together in order to reach a common understanding of the crystalline rocks.

Prof. E. D. Cope discussed the question from a general point of view with especial reference to the value of vertebrates for purposes of correlation, particularly for inter-continental correlation. He pointed out that there is a marked difference in the present verebrate faunas of continents, and that the variation of such forms must be sought in vertical rather than in horizontal ranges. Such study shows that we have had invasions of a given region by a fauna from without ; for example, a South American fauna invaded North America at one time and then retreated, while a North American fauna once invaded South America, and traces of it still remain in that country. He is inclined to believe that certain vertebrate forms did not spread over the earth from a single place of origin, but that they originated at different places upon the earth. We have parallelism in separate places, but the parallelism is defective in the Laramie.

Mr. G. K. Gilbert was of the opinion that many methods of correlation must be used. He doubted the trustworthiness of the correlation of non-fossiliferous rocks by comparative change, even locally. He thought the abundance and scarcity of fossil forms comparable with lithologic differences, and considered the simple occurrence of a species as valuable for purposes of correlation as its abundance.

FIFTH DAY.—Subject for discussion : map-colouring and cartography.

Major J. W. Powell exhibited charts illustrating the colour system used by the U.S. Geological Survey, explained the methods of using the colours, and gave the reasons for them. The colours assigned to rocks of different ages are as follows :—

	Period.	Period colour.	Mark.
1.	Neocene	Orange	N.
2	Eocene	Yellow	E.
3.	Cretaceous	Yellow-green	K.
4.	Jura-Trias	Blue-green	J.
5.	Carboniferous	Blue	C.
6.	Devonian	Violet	D.
7.	Silurian	Purple	S.
8.	Cambrian	Pink	Ꞓ.
9.	Algonkian	Red	A.

The colours are used to designate geologic periods, patterns of these colours designate formations ; minor divisions are usually relegated to the text. The number of patterns for designating formations can be indefinitely enlarged, but follow a definite system.

Mr. Joseph Willcox showed that in the scheme described by Major Powell the colours were not evenly distributed through the chromatic scale.

Prof. C. R. Van Hise pointed out that Archæan rocks are shown by a brown underprint, and that metamorphic rocks of known age are given the colour of the corresponding unaltered rocks.

Major Powell explained that it was not attempted to select colours equally distributed through the chromatic scale, but to use those that may be most readily recognized.

Mr. H. M. Cadell asked why black and gray were not used.

Major Powell replied that blue was used in place of the dark shades for the Carboniferous ; that dark colours are misleading in regard to the occurrence of coal, which occurs in the Cretaceous and Tertiary as well as in the Carboniferous.

Mr. Christie found the black colour very inconvenient, because it often made the details of the map covered by such colours illegible.

Mr. H. M. Cadell said that the maps of the Geological Survey of Great Britain were coloured by hand, and that the system used by the U.S. Geological Survey could not for this reason be economically employed.

Major Powell explained that the U.S. Survey system is very economical when the colour patterns are transferred to stones.

Prof. T. McK. Hughes thought it very difficult to devise a scheme that will meet the demands of everyone. Some reference must be had to the permanence of the colours, the readiness with which they can be applied, and the distinctness with which they show what is desired. He thinks the fittest scheme must survive.

In the afternoon, brief lectures were given by Prof. Chamberlin, Mr. Gilbert, Major Powell, and Mr. Emmons upon the geology of the country to be traversed by the long excursion.

SIXTH DAY.—A Committee on International Bibliography was appointed.

The Secretary announced that Messrs. Golier and Schmidt convey an invitation from the Swiss Government to hold the sixth International Congress, in 1894, in Switzerland. Mr. Golier delivered an address in which he presented the invitation, and the Congress unanimously accepted it. The following Swiss members were appointed a local committee, with power to add to their number and to appoint the time and place of meeting: viz. Messrs. Heim, Renevier, Lang, Balzer, Schmidt, and Golier. On the motion of Prof. Pumpelly, a vote of thanks was passed to the Swiss Government and delegation. It is thought that Berne will be selected as the place of meeting.

The Geological Survey of Russia sent an invitation to hold the seventh Congress in Russia. The Czar joined in the invitation. Prof. Tschernychew made the formal presentation of the subject to the Congress. A vote of thanks to the Survey and the Czar was passed, and the Secretary of the Congress was authorized to send a despatch by cable, transmitting the vote.

The President of the Congress, Prof. Le Conte, delivered a brief closing address, summarizing the work of the session, and after passing several votes of thanks the Congress adjourned.

THE SOCIETY OF FRIENDS OF ASTRONOMY AND COSMIC PHYSICS.

THE Society of Friends of Astronomy and Cosmic Physics, founded May 19, 1891, has been formed with a view to the organization of systematic activity and co-operation in research in the subjects named. It is intended to embrace, chiefly, workers in astronomical science in Germany, Austro-Hungary, Switzerland, and other neighbouring countries, and natives of these countries in the colonies and elsewhere. Members of other nationalities are, however, offered a welcome.

The head centre of the Society is Berlin. The subscription is 5 marks.

Communications are invited from individual members, which will be published together with the notices of meetings and other business of the Society. These publications will bear the title "Mittheilungen der Vereinigung von Freunden der Astronomie und kosmischen Physik"; they will be numbered consecutively, and will be supplied to all members gratis, but will not be issued at regular or stated intervals.

These communications will form at present the only direct publication of the Society, until it is formed on a more substantial financial basis and consists of a larger number of members (in the first four weeks the number rose from 50 to over 100). Contemporaries are at liberty to borrow any matters of interest contained in the Society's communications, of course acknowledging the source from which they are derived.

Endeavours will be made to keep the Society carefully within the limits in which alone it can be successfully active, leaving on one side other closely related branches: for instance, those of the Meteorological and Photographic Societies; but, nevertheless, endeavouring to preserve the closest amity and co-operation with the related Societies.

The Astronomische Gesellschaft, founded in Germany in 1863, is regarded by the new Society as the principal Society, whose office it is to foster astronomical research throughout the whole earth. The new Society bears the same relation to this international association as do those Astronomical Societies already established in England, France, Russia, and North America.

The principal object of these smaller societies is to collect observations made in the largest possible number of districts, inasmuch as researches in astronomy and cosmic physics are very largely dependent on the state of the weather, and the relation of the place of observation to the phenomena in the heavens.

In the new Society the following branches of work have been selected:—(1) Observations of the sun; (2) of the moon and surface of the planets; (3) of the intensity and colour of the light of the stars and of the Milky Way; (4) of the zodiacal light and meteors; (5) of the polar light, magnetism of the earth, earth currents, and air electricity; (6) of the clouds and halos, and thunder and lightning (care being taken in the two last groups not to encroach upon the ground already covered by the Meteorological and Photographic Societies).

Each of these groups is presided over by a member of the Society whose attention is especially directed to the respective subject. The duty of these Presidents is to organize the correspondence, hold branch meetings, and preserve the connection which binds each group to all the others.

The Society will endeavour to further the organization of all these researches, not merely by the publication of communications and by correspondence, but also by advice and aid in the providing of apparatus, especially of suitable optic, electric, and magnetic measuring instruments, charts, books, &c.

The statutes of the Society will be sent post free on application to the Secretary, Herrn Cand. G. Witt, Berlin, N.W., Invalidenstrasse 57.

The President of the Society is at present Prof. Dr. R. Lehmann-Filhés, Berlin, W., Wichmannstrasse 11*a*.

The Committee consists of the six members presiding over the several groups of research.

The Librarian of the Society is Herr Dr. P. Schwahn, Berlin, N.W., Invalidenstrasse 57; and the Treasurer, to whom subscriptions should be sent, Herr Rendant Bruck, Berlin, N.W., Invalidenstrasse 57.

THE PROTECTIVE DEVICE OF AN ANNELID.

AMONGST a gathering of small Serpulids, &c., received from Mr. Sinel, of Jersey, I find some interesting little worms related to the Sabellidæ. They build a thin membrane-like tube, about one-seventieth of an inch in diameter, coated externally with flat translucent particles of sand. Its lower end is closed, and embedded in sponge or other growths, but the upper end is free, and, when the head of the inmate is protruded, stands about a quarter of an inch high in the water. On this head are two branchial tufts, each having five branches beset with a double row of long ciliated filaments. When all are fully expanded they curve backwards, and cover an area of about one-tenth of an inch in diameter. The branches decrease in size from the inner to the outer pairs, and at the back of the longest but one in each tuft, near its base, is a chocolate or brown coloured vesicle. The two smallest branches curve backwards round the mouth of the tube, and keep up a constant whipping or flicking motion.

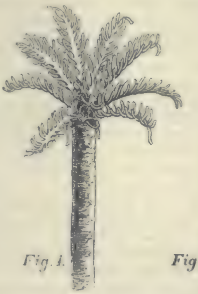

Fig. 1.

Fig. 2.

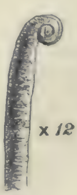

Fig. 3.

But the peculiarity is, that, upon the retreat of the animal, the mouth of the tube not only instantly closes flatly and tightly by collapse of the sides, but the tube itself, beginning at the tip, proceeds to coil up like a spiral spring, looking very much like a young fern-frond. This is, of course, an effectual protection against the intrusion of enemies, and the coiling and uncoiling, which I have witnessed many times, is a most curious sight.

Fig. 1 shows the branchial tufts expanded. Fig. 2, tube beginning to coil up. Fig. 3, tube partly coiled up—a process which is sometimes continued much further. I do not know whether this annelid has previously been noticed or described, but, if so, I shall feel obliged to any of your readers who can refer me to a description. ARNOLD T. WATSON.

Sheffield, August 19.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THERE was at least one very satisfactory feature about the Geographical Section at the Cardiff meeting. It has been the practice in all the other Sections to appoint as Presidents men who have gained a high reputation as specialists in their own departments. For some reason this practice has not been followed in the Geographical Section. True, in past years we have had such men as Murchison, Markham, Galton, General J. T. Walker; but too often the President of this Section, while eminent as a soldier, or a colonial Governor, or as a Society man, has known as much about geography as "the man in the street." It must be admitted that this has in part arisen from the fact that scientific geographers in England could have been counted on the fingers of one hand. Happily, through the recent efforts of the Royal Geographical Society, this is ceasing to be the case, and when the Chairs at Oxford and Cambridge, and the other influences which are at work, have had time to produce results, geography, in one or other of its aspects, may become as much of a career in England as it is in Germany. It was regarded as to some extent a triumph, and an earnest of what is coming, that the President of the Section at Cardiff was a geographer pure and simple. Mr. E. G. Ravenstein has long been regarded as the one scientific cartographer in the United Kingdom (where he has been naturalized for many years); and as a geographer, in the best sense of the term, he is not surpassed. It was natural that in his address he should deal with the progress of the subject in which he is master. His address, while ostensibly dealing with cartography, really showed the growth of our conception of the earth's surface, and indicated the most profitable aspects in which we may deal with that department of knowledge whose business it is to investigate.

Amid a good deal that was trivial, and notwithstanding the usual modicum of sensation, Section E did some solid work at Cardiff. The fact is that the only incident which could be regarded as sensational was the appearance on the platform of Mrs. French Sheldon, evidently suffering greatly from the accident with which she met on her return from Kilimanjaro. But Mrs. Sheldon was able to tell us some things about the people in East Africa that had never come within the ken of the male traveller. Moreover her account of the curious crater lake Chala, at the south-east foot of Kilimanjaro, was a real contribution to geographical knowledge. With immense difficulty she and her companion descended the dense vegetation which covers the precipitous sides of the crater, and navigated the tiny lake on a raft, which was continually in danger from the swarms of crocodiles. Mrs. Bishop (Miss Isabella Bird) was anything but sensational. With perfect calmness and clearness she gave an account of an almost unexplored portion of the Bakhtiari country visited by her, and especially of its interesting inhabitants. Miss E. M. Clerke's paper on the aborigines of Western Australia was more suited to the Anthropological than the Geographical Section, and still more suited to a missionary meeting.

Mr. John Coles's paper on the art of observing showed how comparatively easy it is for any man of average intelligence, and even pupils in the higher classes of our schools, to acquire a knowledge of the use of the more common survey instruments. An excellent paper on the homology of continents was read by Dr. Hugh Robert Mill, who showed that in many respects there is a remarkable family likeness among the continents, arising from the fact that they have been subjected to essentially the same influences. Mr. Silva White, in his paper on the comparative value of African lands, attempted, by a statistical method, to indicate the lines of least resistance against the European domination in Africa. Mr. Miller Christy gave an elaborate and highly instructive paper on the absence of trees from prairies; his conclusion being that the main cause of the treelessness of American prairies has been forest fires. The paper was highly suggestive, showing, as it did, that if proper measures were taken even our great deserts might be made to blossom as the rose.

The greater part of one morning was devoted to a discussion on acclimatization, introduced in a valuable paper by Dr. Robert Felkin. The author showed that there are two schools of thought, the one regarding acclimatization as impossible, the other more sanguine and pronouncing it possible. Probably the truth will be found to be a mean between the two. In considering the subject, it is necessary to specify, first, the various nations who are to be acclimatized, and secondly, the places where they are to be located. As regards the first point, the national characteristics, habits, customs, and environment must be taken into account, and with respect to the second, the nature of the country, its climatology, its inhabitants, their mortality and endemic diseases must be brought under survey. The next point is to classify the various European nations, and it becomes evident that they can only become readily acclimatized in the temperate zone, where climatic and other conditions are approximately akin to their present habitat. In reference to Europeans becoming acclimatized in the tropics, what are those factors which prevent it, or which must be overcome before it is possible? They are as follows: heat, cold, damp, various endemic diseases, especially malaria, and those constitutional conditions induced by climate which either destroy the immigrants or diminish their fertility after one or two generations. Progress has been made during recent years in enabling persons to reside longer and to enjoy greater health in the tropics. What probability is there that science will accomplish still more in rendering acclimatization possible for Europeans in tropical countries? It must be said that both Dr. Felkin and those who followed him in the discussion occasionally lost sight of the real point at issue. The adaptation of a European to tropical conditions for a few years is one thing; the acclimatization of a race in a climate totally different from that which has been its inheritance is another. About the former there need be now no difficulty: what scanty experience we have leads to the conclusion that the latter is practically impossible. What we really want are experiments continued over three or four generations.

Colonel Holdich, of the Indian Survey, gave some valuable hints in his paper on the application of Indian geographical survey methods to Africa. An outline of the methods proposed may be summarized as—(1) The adoption of a rapid system of triangulation along the most important lines for first survey. (2) The extension of a graphic system of mapping from these lines by means chiefly of native labour. The most important lines for first survey are the international boundary lines. Until lately England has been peculiarly free from the necessity of demarcating or maintaining national boundaries. Even India offers but a comparatively short line for defence. The new partition of Africa largely increases her responsibilities in this respect, though there may be no immediate cause for action. There is, however, a great necessity for a topographical acquaintance with the boundaries adopted. Only a small portion of them apparently follow permanent natural features, the rest being defined by rivers, &c. It would appear, then, advantageous to commence triangulation along the boundary lines. This is, however, so far a national or international question, and consequently in these preliminary stages of survey State assistance might very well be expected, and Imperial resources drawn upon for carrying it out. (1) What are these resources? (2) What is the nature of surveys already existing in Africa? (3) What is the nature of the survey we ought to build up? Replying to (2) and (3), we find that if a continuous and comprehensive scheme is to be adopted, with unity of design for all the scattered districts of the African colonial system, nothing has been done as yet which would assist us in carrying out our scheme. This scheme should be largely borrowed from experiences in Asia. A consideration of it shows, in reply to (1), to what extent Imperial survey resources might be utilized during the processes of laying out the preliminary lines of triangulation. From this triangulation the extension of topography would thereafter probably depend on private enterprise. Then followed a short consideration of the general topographical processes as carried out by natives of India, of the value of such native labour, and of the possibility of raising survey establishments in Africa similar to those which have done such excellent work in Asia.

The subject of reform in our Ordnance Survey was again introduced this year in an elaborate paper by Mr. H. T. Crook, who was strongly supported by a number of speakers. Mr. Crook pointed out many defects in the large-scale maps. Some of them are notoriously behind date; they are issued in a most inconvenient form; they are far too expensive; they are difficult to obtain outside of London. The Committee of this Section sent a strongly-worded resolution to the Council of the Association, recommending, among other things, that the Directorship of the Survey, instead of being merely a staff appointment, should be made a permanent office. Unfortunately, the resolution submitted to the General Committee omitted this and other important points, so that in its final form it does not amount to much.

Mr. James Thomson's paper on photography applied to exploration contained suggestions of great practical value. He showed the value of the camera, not only in recording geographical features and types of people, but even as an adjunct to regular surveys.

The subject of geographical education was introduced in a short paper by Mr. J. Scott Keltie, who spoke of the results which had followed the action initiated by the Royal Geographical Society a few years ago. Advances have been made in many directions; Chairs have been established in Oxford and Cambridge; and a higher conception of geography and of its practical utility has begun to prevail. Happily, the attempt to obtain the Section's approval for the foundation of a local Geographical Society in Cardiff failed.

Among other papers worthy of mention were two by Colonel H. Tanner, of the Indian Survey—one on a new method of Bar-Subtense surveying, and a second on some of the principal tribes of the Himalayas.

MECHANICS AT THE BRITISH ASSOCIATION.

IN Section G, Mr. T. Forster Brown, an engineer well known in the locality in connection with mining industry, was the President. There was an average list of papers, but the discussions were not so full as is sometimes the case in this Section. As a consequence, the sittings were got through with more than ordinary speed; there being no meeting on the Saturday, and the whole business of the Section was completed by two o'clock on the Tuesday of the meeting. The President's address was given as usual on the Thursday, and referred to mechanical details in connection with mining. In character with the meeting it was brief. The usual vote of thanks having been moved and seconded, Prof. Osborne Reynolds proceeded to read the third Report of the Committee appointed to investigate the action of waves and currents on the beds and foreshores of estuaries by means of working models. It will be remembered that this Committee arose out of a paper read by Prof. Osborne Reynolds at the last Manchester meeting of the Association; and this, in turn, arose out of the investigations made upon a working model of the Mersey estuary in connection with the then proposed Manchester Ship Canal operations. The further investigations referred to in the last report have been conducted on the same system as previously described. The chief object of this series has been to obtain further information as to the final condition of equilibrium with long tidal rivers entering the head of a ▽-shaped estuary; to obtain more complete verification of the value of the criterion of similarity; to investigate the effect of tides in the generator diverging from simple harmonic tides; and to determine the comparative effect of tides varying from spring to neap. It would be impossible in this brief report of the proceedings of the Section to give an idea of the results at which the Committee arrived, or rather the results shown by the experiments, more especially without the aid of the diagrams by which the Report was illustrated.

The next business was the reading of a paper by Mr. G. Chatterton, in which a sewer was described that has lately been constructed to carry off the sewerage of a neighbouring district, and thus relieve the River Taff of some of its present foul burden. The sewer, no doubt, is a meritorious engineering work, but not one of magnitude or especial novelty. The most notable point is that the Taff has to be crossed seven times, and this is effected by means of inverted syphons which go below the river bed. The principle, of course, is not new. The chief interest was in the speech made by Mr. Baldwin Latham during the discussion, in the course of which the speaker exclaimed against the "faddists" who maintain that what is taken from the earth should be returned to the earth. Mr. Latham is of opinion that what is taken from the earth should be given to the sea. The ocean, he says, was given to the engineer as a receptacle of sewage—presumably among other functions. Moreover, Mr. Latham tells us that it is more profitable to put sewage in the sea than to keep it on the land. It encourages the growth of marine fauna; and it is, so Mr. Latham says, a well-known fact that where there is most sewage there are most fish. As there were no "faddists" present, Mr. Latham had it all his own way.

Mr. L. F. Vernon Harcourt's paper described the engineering operations carried on in the neighbouring River Usk and the harbour of Newport. This paper, again, did not bring forward any points of particular novelty. Mr. Vernon Harcourt is proceeding on the now fairly well recognized lines of increasing the tidal flow. Mr. Abernethy spoke in the discussion, and told the Section how he had once resigned his position in connection with the Swansea Harbour Board because it was proposed to canalize the river. The question might, we think, have been discussed with advantage—although, perhaps, not in connection with the rivers referred to—how far volume of ebb and flow, as compared with velocity, is the ruling factor.

Mr. W. Key, of Glasgow, described the system of ventilation and heating which he had introduced in the Victoria Infirmary, Glasgow. Here, again, we have no new theories enunciated, but the paper was none the less valuable on that account—perhaps more valuable. Mr. Key has taken recognized principles, selecting and arranging in a common-sense manner, and put them into practical shape. The consequence is, we hear, that the atmosphere in the Infirmary is as sweet as that outside—in fact, more so; for, whilst there may be fog in the street and mist on the hill-side, the wards are dry and clear. The circulation of air is by rotary fans driven from a gas-engine. A point upon which Mr. Key strongly insists is a screen down which water is constantly trickling, and which is automatically flushed at intervals. This has the effect of converting dust and other floating particles into mud. The air is heated over steam-pipes in the winter. Admission is 5 feet above ground, and eduction is from the floor-level, so that dust passes off, the air current assisting gravitation.

On the second day's sitting, Friday, August 21, the chief interest was absorbed by Sir Edward Reed's paper, in which he gave certain particulars of the Channel tubular railway, which he proposes some day to construct, supposing the Fates are propitious. If one may believe the eminent engineers who took part in the discussion, the Fates never will be propitious, for Sir Edward violates the first and cardinal rule of engineering enterprise in propounding a scheme that cannot pay. Sir Edward says his double tube, which is to be laid on the bottom of the sea—it is not a tunnel—will cost 12 to 14 millions. Sir Benjamin Baker says that Sir Edward must double his figures, and even then he will not have money enough. It has been stated on the highest authority that the Channel traffic would not pay interest on a million and a quarter spent on harbours; and, if this be the case, there would be a poor prospect for those who would subscribe money for even a Channel Tunnel, far more a tubular railway, and most of all a Channel Bridge, such as Messrs. Schneider and Hersent propose. Sir Edward's scheme is sufficiently heroic. He would construct two mammoth tubes, of steel plate and concrete, 20 feet in diameter. The tubes would be made in lengths, and when two lengths were completed they would be joined together in parallel, 50 feet apart, and floated out into the Channel to be attached to the completed length. The first part of the construction, near the shore, would not be difficult, but if ever Sir Edward gets out into deep water, say 200 feet, he will find troubles enough. All work is to be done above water. Thus the end of the completed part of the double tube will be kept afloat until a fresh length is joined on. Then that will be allowed to sink, and the last attached part will form the end of the completed part. In this way, so long as the work of construction is in progress, the part of the tubes last completed will slope up from the sea bottom to the surface, so that the next length may be attached. The scheme is splendid in its disregard of difficulties. It is worthy of the fervid genius of Jules Verne.

Prof. W. Robinson next read a paper on petroleum engines. It would appear that this description of motor is likely to come to the front, if one may judge from the fact that their manufacture is being taken up by some important engineering firms. Priestman Bros., of Hull, have been at work on the problem for the last year or two, and it is chiefly of the Priestman engine that Prof. Robinson speaks. Crossley Bros., of Manchester, who have made such a brilliant success with the Otto gas engine, have now taken up the subject, and are making an oil engine; whilst the big agricultural engineering firm, Hornsby's, of Grantham, have also turned their attention in this direction. There have also been efforts made by foreign engineers. A petroleum engine works generally on the same principle as a gas engine, but the chief trouble, we believe, hitherto has been to get over the clogging of parts. This supplies the chief feature in the Priestman design, in which there is a spray maker specially designed to get over this trouble. A jet of oil is first broken up by compressed air, and the spray is then further mixed with air, heated by the hot products of combustion. To cleanse the air it is drawn through cotton wool, which naturally has to be renewed from time to time. The proportions of air and oil vapour are arranged to give an explosive charge, and a regular explosion is obtained every cycle by means of an electric spark. The cylinders are water-jacketted. Messrs. Priestman have fitted a pair of their oil engines into a small launch, which is said to have answered well. Whether petroleum used explosively in an engine afloat will ever oust our tried but very imperfect servant steam—as the gas engine is superseding the steam engine in so many positions ashore—is a very open question. Certainly it is a great temptation to get rid of the heavy and bulky boiler, which takes up so much room in a boat, but much remains to be done before we can arrive at the more logical method of generating heat energy in the place where it has to be used. It may be that that terrible exhaustion of our coal-fields, about which we heard so much at the meeting of the Association, will be indefinitely postponed by the using of petroleum or other hydrocarbon as a source of motive power. But that is another story.

Mr. Beauchamp Tower described some improvements in detail which he has introduced in the design of that beautiful piece of mechanism by which he has secured to us, by means of gyroscopically-controlled hydraulic gear, a steady platform at sea; and Prof. A. C. Elliott read a paper on the transmission of power by compressed air. Dr. William Anderson described his revolving water purifier; and Mr. Faija gave a long account of many points in connection with Portland cement. These were all the papers read on Friday.

On Saturday there was no meeting in Section G, and Monday was, according to custom, devoted to electrical matters. Mr. W. H. Preece opened the proceedings with a long paper, or rather lecture, on the London and Paris telephone, in the course of which he was enthusiastic upon the success which had been obtained. He is sanguine that before long we shall be able to talk between London and Berlin. Of course, he improved the occasion by insisting on the necessity of metallic returns, a point upon which all will agree with him except shareholders in telephone companies. Naturally, also, Mr. Preece did not fail to hint how much better off the British public would have been had telephone exchange been left in the hands of the Post Office. No doubt, if all the telephones were now transferred to Mr. Preece's guidance, we should sooner have metallic returns, and Christian patience would be less exercised; but the question may arise whether we should have had any telephones at all now if Government monopoly had not been broken through. With Mr. Preece as the controlling factor, we should answer "Yes." But there are other sorts of Government officials than Mr. Preece.

Mr. Bennett's paper on the telephoning of great cities referred mostly to the arrangement of details of exchange.

Prof. G. Forbes read a long paper, in which he gave an account of recent progress in the use of electric motors. It was of an interesting nature, and dealt largely with the advance that has been made in America. We trust Mr. Forbes is better acquainted with Transatlantic electrical practice than he is with one branch, at least, of British practice; for when he said, as we understood him, that there are no electrical cranes in England, he was certainly wide of the mark.

Papers by Mr. N. Watts, on electric fire-damp indicators, and by J. A. Timmis, on electric lighting in trains, were also on the list.

On Tuesday, August 25, Section G held its last sitting, and there was a varied selection of papers. The first was a contribution by Mr. A. R. Bennett, in which he advocated a system of house-to-house parcels distribution, which would certainly be very convenient if it could be carried out. He proposes tunnels under the street with miniature electric railways. That would be a difficult thing to arrange in any of our cities, the space being so occupied by gas- and water-pipes, sewers, electric wires, hydraulic mains, and many other things, were the tunnels simply to be run straight away with only stations at distant points; but Mr. Bennett proposes to make this a house-to-house service, each subscriber having his own siding. The tube would be rectangular, with two lines of rails one above the other. By means of semaphores at the central station, worked electrically by the passage of the train, so that the operator can always tell where the train is, and by further electrical connection he is able to shunt the train into the subscriber's own siding. When one subscriber wants to send a parcel to another, he procures a truck, and despatches this through the tunnel to the central station, from whence the operator forwards it to the right address. There is even an arrangement for unloading automatically, and the truck can then be brought back by the operator without the intervention of the subscriber. The idea is fascinating, and we may say that it appears quite practicable; but it will not come yet. Some day, when we determine to pull down and rearrange London—as manufacturers throw aside obsolete but perfectly sound machinery to gain the economy of some newer designs—Mr. Bennett's electrical exchange may come in; and then the blessing it will be to the community will be incalculable. We can have a five minutes collection and delivery of letters; butcher-boys will no longer whistle at the side door, and the baker will cease to scribble on the gate-post.

Mr. W. Worby Beaumont next read a paper on internal and external work of evaporation. This is one of a series of monographs which the author has prepared on this subject, but the matter is too abstruse for us to deal with in this very brief account of the four days' meeting. Were we to attempt to abstract the paper, it might lead us into controversial matter.

Major R. de Villamil's paper on the action of screw-propellers was a praiseworthy effort to accomplish the apparently hopeless task of lifting the practice of designing the screw-propeller from the region of empiricism—where it has always dwelt—to the domain of pure science. We fear, however, in spite of it, that the marine engineer will still adhere to the ancient rule-of-thumb by which alone he is now guided. It is curious that the man who has done most to improve the design of the screw-propeller was essentially non-scientific. He made his chief discovery in an endeavour to do one thing, but produced the reverse result. When Griffith first used the spherical boss, he was trying to produce a retarding effect, but found, on trial, that he had added greatly to the efficiency of the screw.

Mr. Beaumont also read a paper on the screw-propeller. He described a method of reversing the direction of thrust by means of feathering-blades, on the well-known Bevis principle. The advantages claimed were that, as the engines and screw would be always running in one direction, there would be no momentum of moving parts to be overcome when it was desired to go from ahead to astern, or *vice versâ*, and therefore there would be less danger of breakage of the mechanism. The proposal was somewhat roughly handled in the discussion which followed, but we think that Mr. Beaumont fairly held his own in his reply. The most valid objection appeared to be that of Mr. Heard, who pointed out that the pressure on a given area of the blade was by no means constant throughout each revolution, and the disturbance would cause the joints of the mechanism to wear. For this reason there would be introduced an undesirable and even dangerous play on the pins after the apparatus had been in use some time.

A paper upon non-conducting coverings for steam-boilers having been read, the business of Section G was brought to a close with the usual votes of thanks.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE proceedings began with the President's address, after which Prof. R. K. Douglas read a paper on the social and religious ideas of the Chinese as illustrated in the ideographic characters of the language. After a short introduction, showing that the Chinese ideographic characters are picture-writings, the author gave an account of the earliest or hieroglyphic form of the writing, the development of this resulting in the ideographic characters. The social habits of the people and their domestic life were illustrated by a number of ideograms descriptive of their household arrangements and relationships. The author traced in the written characters the ideas associated with men and women, their virtues and their failings; the notions connected with marriage; and the evidences of pastoral as well as of agricultural habits among the people. The paper concluded with references to the coinage of the country as described in the ideograms employed to represent its various forms.

The following papers were also read: on recent progress in the analysis of vowel-sounds, by Dr. R. J. Lloyd; family life of the Haidas (Queen Charlotte Islands), by the Rev. Charles Harrison; and the Report of the North-Western Tribes of Canada Committee. This last is again the work of Dr. Franz Boas in the interesting ethnological field of British Columbia. It consists of two parts, the first being devoted to the Bilqula, a people inhabiting a limited tract in the vicinity of Dean Inlet and Bentinck Arms, the second dealing with the physical characteristics of the tribes of the North-west coast region.

Prof. Max Müller then made some remarks on the work of Major J. W. Powell, Director of the U.S. Bureau of Ethnology. He said that he had just received the proof-sheets of a most important publication on the classification of the Indian languages spoken in America. It is a splendid piece of workmanship from Major Powell, the indefatigable Director of the American Bureau of Ethnology. The publications of that Bureau count amongst the most valuable contributions to anthropological science, and they reflect the highest credit, not only on Major Powell and his fellow-workers, but also on the American Government, which has sanctioned a very large outlay for the prosecution of these studies. There is no stint in the way these volumes are brought out, and most of the papers contained in them inspire the student with that confidence which can only be produced by honest, conscientious, and truly scholarlike work. Our American friends have perceived that it is a national duty to preserve as much as can still be preserved of the languages and thoughts of the indigenous races who were the earliest dwellers on American soil. They know that the study of what Prof. Max Müller ventured to call intellectual geology is quite as important as that of terrestrial geology, and that the study of the lower strata contains the key to a right understanding of the higher strata in the growth of the human mind. Coming generations will call us to account for having allowed the old world to vanish without trying to preserve its records. People who ask what can be the use of preserving the language of the Mohawks forget what we would give if some scholar at the time of Cato or Cæsar had written down, what many could then easily have done, a grammar of the Etruscan language. Some years ago the author had succeeded in persuading a Secretary of State for the Colonies that it was the duty of the English Government to publish a series of colonial records, containing trustworthy information on the languages, customs, laws, religions, and monuments of the races inhabiting the English colonies. Lord Granville saw that such an undertaking was a national duty, and that the necessary funds should be contributed by the various colonies. What a magnificent work this would have been! But while the American Government has pushed forward its work, Lord Granville's scheme expired in the pigeon-holes of the Colonial Office. America may well be proud of Major Powell, who would not allow the treasures collected by various scholars and Government officials to moulder and perish. He is a true enthusiast, not a man of mere impulse and good intentions, but a man of sustained effort in his work. He deserves the hearty thanks of the Association, and more especially of the Anthropological Section.

The whole of Friday morning was occupied by a paper by the Marquess of Bute, on the language of Teneriffe. The difficulties in the study of the language are due to the fact that the aboriginal words have been collected from *all* the islands without indicating their several origins, so that the Teneriffe words were not at first easily distinguished. Students hitherto have held three opinions as to this language. The first is that of Dr. Glas, who considered the language American (and the people African); the second, advanced by Sir Edmund Scory, classed the language and people as Berber; while the third holds that the Teneriffians were of Aryan origin.

Dr. Edward B. Tylor read a paper on the limits of savage religion. It has lately become clear by the inquiries of anthropologists that the world-famous Great Spirit of the North American Indians arose from the teachings of the Jesuit missionaries in Canada early in the seventeenth century. This and analogous names for a Supreme Deity, unknown previously to native belief, have since spread over North America, amalgamating with native doctrines and ceremonial rites into highly interesting but perplexing combinations. The mistaken attribution to barbaric races of theological beliefs really belonging to the cultured world, as well as the development among these races of new religious formations under cultured influence, are due to several causes, which it is the object of this paper to examine: (1) direct adoption from foreign teachers; (2) the exaggeration of genuine native deities of a lower order into a god or devil; (3) the conversion of native words, denoting a whole class of minor spiritual beings, such as ghosts or demons, into individual names, alleged to be those of a Supreme Good Deity or a rival Evil Deity.

Mr. H. Ling Roth read a paper on *couvade*, in which he gave an account of the distribution of this curious custom, and showed that the savage believes that there is some hidden link which binds the new-born child to its father, and he argued that the practice of *couvade* is to prevent the father bewitching his child.

In a paper by Mr. S. E. Peal, on the *morong* and other customs of the natives of Asam, the author shows that this institution of the *morong*, or club-house for the unmarried, is very widely distributed over the whole of the Indo-Pacific region, and he argues that it is, in fact, a relic of pre-marriage communism. Moreover, this custom being so often found associated with others of a distinctly non-Aryan character, such as juming, tattooing, blackening the teeth, building on piles, head-hunting, &c., has led him to suspect former racial affinity, even among such widely different types as Papuan and Mongol, Dravidian and Sawaiori.

A paper by the Rev. B. Danks, on the burial customs of New Britain, was read.

In a paper on the worship of meteorites, Prof. H. A. Newton, on Monday, gave a series of accounts of divine honours having been paid to meteoric stones in early times, and of myths and traditions pointing to such worship. Particular attention was directed to the indications of such worship that are found in Greek and Roman history and literature.

Dr. Garson read a paper on some human remains found in Yorkshire. He dealt principally with a round barrow in which skeletons with very long skulls had been found. These skulls were much longer and narrower than the heads of the existing inhabitants of this country, and corresponded with those of the Iberians. The average height of the persons whose skeletons were found in this barrow was a little over 5 feet 3 inches. The discovery of flint and the absence of iron implements showed that the burial took place before the use of metals. The Iberian people were short, had dark hair, straight noses, flat foreheads, and no ear-lobes. It was a race quite distinct from the Celtic type, which afterwards came in and drove them further westwards into forests and swamps.

A paper by Miss Buckland was read, on points of contact between Old World myths and customs and the Navajo myth entitled "The Mountain Chant." The author drew attention to the numerous points in which this myth reproduces customs and beliefs of the Old World. Among these were mentioned the singular prohibition of food in the abode of spirits, such as appears in the classical story of Persephone, but which is found slightly modified in the fairy folk-lore of Europe, in Aino and Japanese tales, and in New Zealand. Miss Buckland points out the great contrast between the bloodless Navajo rites and the sanguinary ceremonies of the ancient Mexicans, and the great dissimilarity in the forms of the Navajo and Mexican gods, as denoting an entirely different origin for the two religions, incompatible with the belief commonly entertained of the wholly indigenous character of American culture; and she urges that the Navajo rites point unmistakably to an Eastern origin.

A paper by the Rev. James Macdonald, on East Central African customs, was read. The customs dealt with ranged over the whole domestic and social life of the people.

The following papers were also read:—Prof. G. Hartwell Jones, barbaric Greece and Italy; J. E. Budgett Meakin, the Berbers of Morocco; Dr. J. S. Phené, a comparison of ancient Welsh customs, devices, and commerce with those of contemporary nations; W. M. Adams, the first sea-wanderings of the English race. The Report of the Prehistoric Inhabitants Committee, and the Report of the Elbolton Cave Committee, were also read.

On Tuesday, Dr. Garson read a paper on M. Bertillon's method of criminal anthropometry, in which he described the plan now adopted by the French police for the identification of criminals.

Dr. S. A. K. Strahan read a paper on instinctive criminality, its true character and rational treatment. The instinctive criminal belongs to a decaying race, and is only met with in families whose other members show signs of degradation; in fact, instinctive criminality is but one of the many known signs of family decay. Not only is criminality hereditary, but it is interchangeable with other degenerate conditions, such as idiocy, epilepsy, suicide, insanity, scrofula, &c., and it is a mere chance whether the insanity or drunkenness, say, of the parent, will appear as such in the child, or be transmuted in transmission to one or other of the above-mentioned degenerate conditions. Alcoholism is the most fruitful source of instinctive criminality, but insanity, epilepsy, and suicide are often transmuted to crime in passing to the children. Senility and immaturity of parents are also fruitful sources of crime in the enfeebled descendants, as is proved by the statistics of Marro, Korosi, and others. The present system of treatment has proved a disastrous failure; short periods of punishment can have no effect upon the instinctive criminal, either curative or deterrent. Everything points in the direction of prolonged or indefinite confinement in industrial penitentiaries. This system has been tried with success in America, and life-long detention has not been found by any means necessary.

Nicobar pottery, by E. H. Man. In this paper Mr. Man stated that the little island of Chowra has held for generations a monopoly of the manufacture; and the entire work of preparing the clay, as well as of moulding and firing the finished utensil, devolves on the females of the community. The inhabitants of the island appear to guard their art jealously, and the value of trade-marks is recognized. No vessels are made especially by the Nicobarese for funeral purposes, but cooking pots are among the personal and household requisites which are laid on a grave after an interment. They have no knowledge of any implement answering the purpose of a "potter's wheel."

The following communications were also received:—E. Seward, on the formation of a record of the prehistoric and ancient remains of Glamorganshire; Dr. J. S. Phené, on recent Hittite discoveries; Mrs. S. S. Allison, account of the Similkameen Indians of British Columbia; Report of the Anthropometric Laboratory Committee; Report of the Anthropological Notes and Queries Committee; and the Report of the Indian Committee.

SCIENTIFIC SERIALS.

THE *American Meteorological Journal* for September contains the concluding part of an article on mountain meteorology, by A. L. Rotch. The subjects specially treated of are wind and temperature in connection with atmospheric pressure, as observed chiefly at the Blue Hill Observatory. The wind velocity is found to be two-thirds greater there than at Boston, about 500 feet lower, but the difference changes for various hours of the day. At low levels the wind force generally increases from the early morning until the afternoon, but the conditions are reversed at higher levels. This fact was pointed out by Prof. Hellmann in 1875, when studying the Mount Washington observations, and the same fact has since been observed at Ben Nevis and other Observatories. The wind has also a vertical as well as a horizontal motion, which has amounted to seven miles an hour in a storm. The normal temperature at the summit of Blue Hill is 2° lower than at the base, giving a decrease of 1° for each 220 feet of ascent, but inversions frequently occur, when the temperature of the base is lower than at the summit. Instances of this are given, together with records obtained during balloon ascents.—The aspiration psychrometer and its use in balloons, by Dr. R. Assmann. Such an instrument was first used by Welsh in 1853, but it was not fully adapted to use in balloons. The apparatus invented and described by Dr. Assmann, which is intended to register the changes, which ordinary thermometers do not show quickly enough, is made by Fuess, of Berlin. The aspirator may be driven by a small electric motor, instead of by clockwork.—The Bergen Point tornado, by W. A. Eddy. The track was about nine miles south-west of New York City, on June 16 last. The tornado was preceded and followed by showers of large hailstones, and extended only for about two miles.—The hot winds of California, by Lieutenant J. P. Finley. The period during which these winds occur is from May to September; the thermometer has been known to reach 118° in the shade, and the winds generally occur during entire absence of clouds.—Altitude and hay fever, by Dr. W. J. Herdman. Special attention is drawn to the curative influence of mountain stations.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 14.—M. Duchartre in the chair.—Recent discussions on the subject of cyclones, by M. H. Faye.—A contribution to the botanical history of the truffle—*Kammé*, from Damas (*Terfezia Claveryi*), by M. A. Chatin. A description of a new species of truffle—the white truffle of the desert, known in Syria under the name *Kammé*. It has a wide range, the same species as this found near Damas having been also seen in the desert 400 miles south of Biskra. It forms an important article of food.—On the incandescence of platinum wires under water, by M. Paquelin. A mixture of hydrocarbon vapours and air is led over a specially arranged platinum apparatus, which becomes heated almost to its fusion point, and will then remain luminous if suddenly plunged into water.—Observations of the Comet Wolf, 1884 III., made by the *coudé* equatorial (0·36 m.) of the Lyons Observatory, by M. G. Le Cadet.—On the yeast of wine, by M. A. Rommier. Experiments made on the production of wines from vines of the same stock grown in different districts lead to the conclusion that the ferments producing the characteristic bouquet in wines of different districts, are peculiar to those districts and are not carried to new districts readily by the transplantation of the vines.—On the determinism of sexuality in *Hydatina senta*, by M. Maupas.

THURSDAY, OCTOBER 1, 1891.

THE BACTERIOLOGICAL EXAMINATION OF WATER.

Manuel Pratique d'Analyse Bactériologique des Eaux. Par le Dr. Miquel. (Paris: Gauthier-Villars et Fils, 1891.)

THERE is probably no body of scientific men amongst whom national feeling and prejudice are so little under control as the workers in the domain of bacteriology. In perusing memoirs, text-books, dictionary-articles, and literature of every kind bearing upon this infant science, the reader must almost invariably take into consideration the language in which they are written, more especially whether German or French; and if the author belongs to neither of these rival nationalities, it is not unfrequently desirable to ascertain in which of the two camps he has been educated, for, unless this be made allowance for, a warped and often erroneous impression will be carried away.

The present work certainly forms no exception to this state of things; indeed, this phenomenon of party-spirit is regrettably prominent. Thus, in reading one of the first paragraphs, beginning with "Les premières statistiques relatives à la richesse bactérienne des eaux furent publiées par moi," and, indeed, throughout these pages we are reminded of the words of the deeply lamented *savant* who commenced his monumental work with "La chimie est une science française," and perhaps even more of the famous utterance, "L'état, c'est moi!"

Dr. Miquel's treatise, consisting of 194 pages, is divided into five chapters, dealing respectively with (1) the collection of samples, (2) the transport of the collected water, (3) the quantitative analysis, (4) the qualitative analysis, (5) the interpretation of the results obtained. On these subjects Dr. Miquel should be well qualified to write, because, as he informs us, it is only in his laboratory at Montsouris that the bacteriological examination of water has been carried on over a period of eleven years. Indeed, we know of no bacteriologist who has so entirely devoted his attention to the subject of micro-organisms in air and water as Dr. Miquel, whose name is so inseparably connected with "les organismes vivants de l'atmosphère." His energies have, however, apparently not been so successfully directed to the aquatic as to the aërial microbes, for we do not connect Dr. Miquel's name with any of the more important advances that have been made in our knowledge of the bacteria in water during the past ten years. The comparative sterility of Dr. Miquel's researches in this direction is perhaps partially to be accounted for through the extraordinarily cumbrous method of water-examination which he formerly exclusively employed, and which has placed him at a great disadvantage by the side of those investigators who at once availed themselves of Koch's methods, which Dr. Miquel, like many other French bacteriologists, has only adopted with reluctance, or almost under compulsion. The chief interest attaching to the bacteriological examination of water lies in its application to the hygiene of water-supply, inasmuch as it is all but certain that two at least of the most fatal zymotic diseases—cholera and typhoid—can be, and are, constantly propagated through the presence of specific micro-organisms in water, and indeed the majority of bacteriologists are agreed as to the particular forms responsible for these diseases. On this account it is conceived by many that the primary object of the bacteriological examination should be the search for such pathogenic microbes. This view is apparently endorsed by Dr. Miquel when he says, "Le but que doit poursuivre le micrographe dans les analyses bactériologiques de l'eau est sans contredit la découverte des organismes pathogènes"; although the logical conclusion to be drawn from the pages which follow, and in which he details the methods to be pursued in this quest, is that such an investigation is generally fraught with insuperable difficulties, and, for sanitary purposes, practically worthless. Thus, without wishing to detract from the importance of the discovery by Chantemesse, Widal, and others of the typhoid bacillus in certain waters which had been suspected of propagating this disease amongst their consumers, it is surely obvious that, even if this organism could be detected with unerring certainty in any water in which it was present, a search for this bacillus in the ordinary course of water examination would still have only a very subsidiary interest. Waters are surely not only to be condemned for drinking-purposes when they contain the germs of zymotic disease at the time of analysis, but in all cases when they are subject to contaminations which may at any time contain such germs. Sewage-contaminated waters must on this account be invariably proscribed, quite irrespectively of whether the sewage is, at the time that the water is submitted to examination, derived from healthy or from diseased persons. In the present state of our knowledge there can be no doubt that chemical analysis affords us in general a better, although a far from perfect, indication of sewage contamination than do the results of bacteriological examination. The real value of these bacteriological investigations, if judiciously applied, consists in their power of furnishing us with information as to the probable fate of dangerous organisms, should they gain access to drinking-water. It is by their means that we have learnt that many such organisms can preserve their vitality, nay, in some cases can actually undergo multiplication, in ordinary drinking-water; that they are destroyed by maintaining the water at the boiling-point for a short time; and that they are more or less perfectly removed by some processes of filtration and precipitation, whilst other processes of the same nature are worthless, or even worse.

These important results are of the greater value inasmuch as they have been obtained not only by experimenting with the few pathogenic organisms with which we are at present acquainted, but by studying the effect of these several processes on the complex mixtures of micro-organisms that are to be found in natural waters. The rapidity with which this knowledge has been acquired is due to the quantitative accuracy combined with facility of manipulation which characterize the method of gelatine-plate culture. It has been repeatedly urged against this method that it is incapable of revealing many well-known forms of bacteria which either do not grow in the gelatine-peptone medium at all, or at any rate not at those temperatures at which it still remains solid, and it is in this respect that Dr. Miquel claims superiority for his infinitely more laborious method of "ensemencements fractionnés" in bouillon. It is obvious that labour must be no consideration if any great scientific advantage is to be attained; but, on the other hand, the unnecessary complication of processes, without corresponding benefits, must invariably lead to the retardation of scientific progress. Now, it would certainly appear that the benefits obtained by Miquel's process are in no way commensurate with the additional labour which it entails. Thus, his process is also incapable of revealing all the microbes which may be present in water, and yields at best only a closer approximation to the total number than does the gelatine method. For the general purposes of the bacteriological examination of water, however, it is of very little consequence whether the method employed reveals, say, 30, 50, 70, or 90 per cent. of the total number of microbes present, all that is required being a result which will serve for comparison. Thus, supposing it is desired to ascertain the efficiency of some process of filtration, provided that the unfiltered and filtered waters respectively are submitted to the same method of examination, the comparative result will be the same whether 50 per cent. only or all the microbes present are in both cases enumerated. Thus putting this statement to the test of actual experiment, from the results of the gelatine-plate method of examination I reported to the Local Government Board in 1886 that the average reduction in the number of micro-organisms present in Thames water effected by the sand-filtration of the several London water companies amounted to—

98·6	per cent.	for the	Chelsea Company,
99·1	,,	,,	West Middlesex Company,
96·7	,,	,,	Southwark Company,
98·2	,,	,,	Grand Junction Company,
96·2	,,	,,	Lambeth Company,

whilst Dr. Miquel in 1890 gives as the effect of sand-filtration on the water of the River Loire a reduction of 99·3 per cent. in one case, and 99·4 per cent. in another case. A concordance more complete than this can certainly not be demanded. Similarly it can be shown that Dr. Miquel's method of water examination has not yielded any results of importance which had not already been arrived at before by other investigators using the more expeditious method of plate cultivation. It is indeed only for such differential experiments as that referred to above that the bacteriological examination of water, in the present state of our knowledge, is really of much value, for any judgment as to the purity or otherwise of a sample of water based upon the actual number of microbes found in a given volume of it, is liable to lead to the most serious errors, in consequence of the remarkable power which some bacteria possess of multiplying to an extraordinary extent in waters of the greatest organic purity; in fact, it is precisely in the purest waters that such multiplication is often most pronounced. It is the possibility of such multiplication taking place which renders it imperative that samples of water should be submitted to bacteriological examination within a few hours of their collection. In order to overcome this difficulty, which has hitherto debarred the examination of waters from distant sources, Dr. Miquel has the samples transmitted in a box surrounded with ice; to this there are manifold objections, for the low temperature thus secured by no means completely arrests the multiplication of some bacteria, whilst it causes the destruction of others. Dr. Georg Frank, of Berlin, on the other hand, seeks to overcome the difficulty by deputing to persons on the spot the task not only of collecting the samples, but also of preparing the plate-cultures; but, considering the nature of the instructions which he finds it necessary to give to the novices to whom this work may fall, the expedient does not appear very promising. The following is a verbatim extract from these instructions recently published in a German scientific journal of repute, which surely demands no comment:—

"The person commissioned with the collection of the sample takes off his coat, turns up his shirt-sleeves on both arms, fastening them so securely that they cannot fall down of themselves. Then he washes his hands and arms most carefully with soap and brush to above the elbow-joint. Special care must be bestowed upon the cleansing of the finger-nails, which must if necessary be treated with the nail-file. Finally, the person in question dries himself with a clean towel."

We take it that the value of results depending upon manipulations carried out by persons requiring these instructions would be such that it would be no loss if they were dispensed with altogether. Indeed, unless the bacteriological examination of water be invariably carried out by qualified persons, and by them employed only in cases where it is really capable of rendering service, it is certain to fall into that disrepute which has so frequently been drawn down upon the chemical examination of water through incompetent analysts. Indeed the bacteriological method has already seriously suffered in public estimation through the contradictions which have resulted from the attempts made in some quarters to classify waters according to the number of microbes revealed on cultivation. Such arbitrary standards have already done much mischief in the case of the chemical analysis of water; in the bacteriological examination they are still more reprehensible, and it is deeply to be regretted that Dr. Miquel, in this most recent work on the subject, should seek to perpetuate a system of standards which experience shows to be quite untenable.

The work concludes with some excellent recommendations as to the sterilization of water for drinking-purposes, a subject which cannot be too frequently brought into public notice, for, using Dr. Miquel's own words, "la vie d'un homme a bien sa valeur à côté du prix insignifiant auquel revient le litre d'eau purgée de germes qu'il peut consommer en vingt-quatre heures."

PERCY F. FRANKLAND.

EPIDEMIC INFLUENZA.

Epidemic Influenza: Notes on its Origin and Method of Spread. By Richard Sisley, M.D. (London: Longmans, Green, and Co., 1891.)

THE object of this brief treatise, which was prepared before the issue of the Report of the Local Government Board, is to prove the doctrine, widely held by physicians of eminence in the eighteenth century, that influenza is contagious, or, more strictly speaking, infectious, and therefore, in the opinion of the author, fit to be included among the diseases of which notification is locally compulsory. The book is somewhat peculiar in its arrangement, but in the essential qualities of impartiality and clearness leaves nothing to be desired. Many readers who do not require more than specimens of evidence, will thank Dr. Sisley for compressing the digest of "many thousands" of notes into such narrow compass; but other minds will require a chain of which every link is massive, to guide them to the point of view whence practical conclusions are palpable. If the manner of statement is somewhat bare, and examples rather scanty, in the exposition of a strong but disputed case, the facts brought forward bear none the less value in their neutral setting, and go far to justify the proposition with which he confronts us at the outset, derived from a study of the distribution of the disease and from its pathological character. Valuable assistance from Dr. Klein, Prof. Fleming, and many others, has enabled him to include in his pages some interesting matter relating to the microbic nature of the epidemic and its relation to a similar disease in animals. After all that has been conjectured on the latter point, it appears that evidence of any unusual prevalence of influenza among animals at the time is still wanting.

The original seat of influenza, which has been obscurely indicated in previous times as lying somewhere "in the East," has now been discerned in Mongolian and Chinese territory, for we have two independent accounts, each speaking of influenza as not uncommon in some parts of China. In Mongolia "it seldom proves fatal, but travellers are careful to avoid it, and no one would think of using the pot or ladle of a family suffering from this sickness." If the disease is sporadic and endemic in these countries, the population may be to some degree protected against epidemic outbreaks, for we have seen in Europe that the tendency to spread is much less marked in a second invasion occurring within one year, and least, on the whole, in those places where it was previously most severe.

The notes from Bokhara, translated in this volume, are of great importance, for they show how a wet spring had turned the neighbouring country into a perfect marsh, from which, when the hot weather set in, poisonous exhalations were given forth, and how the people, crowded together with horses, cattle, and sheep between high walls, distressed and weak with starvation and disease, were attacked much earlier than usual, in the first heat of summer, with malaria, and how this was quickly followed by an epidemic of influenza, reaching its height in July 1889. The extension of the disease westwards from Bokhara by the flight of convalescents to Russia, and eastwards by caravans to post-stations in Siberia, has been noticed in the official Report, and completes the evidence connecting the European epidemic with the miserable condition of an Asiatic town. Upon such a soil, influenza sprang into fatal activity, and acquired, as we may fairly infer, a particular virulence. In similar conditions, amid the filth, floods, and famines of Asiatic countries, cholera and other plagues of men and animals have been evolved and have set forth on their destructive march.

By reports from several medical officers, and by a number of charts showing the curve of prevalence of the disease in English and foreign cities, Dr. Sisley shows that we have no experience of any sudden prostration of a large population within a few days, such as was formerly supposed to occur; but that the rise is always gradual from a few cases to hundreds and thousands, the maximum usually occurring from one to two months after the first cases in the locality have been noted. Last century Dr. Haygarth had been fortunate in discovering the person who brought the infection to each place in his district. If equal pains had been taken in 1890, when the disease was on its way to us from Russia, the persons who conveyed it from country to country might, no doubt, have been identified. The author has not been able to find a single instance in which there was a sudden infection of a large number of people without the previous existence of cases of the disease; and wherever its course was studied with care, it was seen to spread in the same way as other infectious diseases. But the "atmospheric" doctrine, though previously disproved with regard to rabies, cholera, and pestilence in general, still finds a stronghold in consumption and influenza.

The classic examples of ships supposed to have been attacked on the ocean by wind-borne influenza, as well as those of towns supposed to have been prostrated "in a single day," really bear testimony to the insidious growth of the disease and to the necessity of early recognition. Neither in this volume nor in others on the same subject is the fact sufficiently dwelt upon, that the geographical distribution of this and of previous epidemics in successive weeks and months was wholly unlike what would have occurred if the germs had been largely spread, either by lower or by upper atmospheric currents.

The total exemption of lighthouse-keepers, deep-sea fishermen, and unvisited islands, is scarcely noticed by Dr. Sisley, but he considers the rarity of influenza among prisoners to have been due to their removal from sources of contagion, and relates a very interesting case of apparent infection of a man on his way home from a light-ship through contact with the crew of a fishing-boat, said to be in good health.

Dr. Sisley concludes that there is no convincing proof of transmission through unaffected persons, letters, &c.; but a series of cases each of considerable weight surely amounts to evidence strong enough to justify some precautions, such as would be taken with the organic dust from more serious diseases, *e.g.* scarlet fever and diphtheria, which are so transmissible. There is happily a great deal in common in the mode of spread of most zymotic diseases, and disinfection as usually practised could hardly be misapplied to influenza. The same may be said with regard to isolation, for no attack, however trivial in itself, is a matter of indifference to the public, if it may result in widespread illness, loss of work, and distress. A short retirement is desirable in the interest both of the patient and of the public. But Dr. Sisley can hardly desire that notification should take place on exactly the same lines as that of other diseases, for local authorities would with reason wince at the expense; and unless the notification were a national undertaking, no district would be adequately protected thereby from imported cases. Complete and national measures of notification and isolation, with the co-operation of local authorities, would be much more likely to be effectual. An expenditure of one-fiftieth of the cost of the recent epidemic would probably secure the country from any such infliction in future. But we must admit that without a somewhat strict supervision at ports of entry during the period of prevalence in other countries, and without provision for the segregation of slight or suspected cases during that period, mere notification would not be likely to put a stop to the spread of influenza. The early cases are worth taking a great deal of trouble to discover and isolate. When once many cases have occurred in a locality, the further progress of so protean a disease is difficult to arrest. The best chance of averting an epidemic must be sought in scrupulous care for early isolation, in tracing the movements of travellers from infected towns, and in the increased practice of ventilation in private houses and in public gatherings. Like typhus, influenza seems incapable of inflicting much damage except through the medium of close, confined, and impure air, and where measures of isolation and disinfection are used it seldom spreads. But the infectious character of influenza must be internationally recognized before protective regulations can achieve a full measure of success.

R. RUSSELL.

GENERAL CHEMICAL MINERALOGY.

Allgemeine Chemische Mineralogie. Von Dr. C. Doelter, O. Professor der Mineralogie an der K. K. Universität Graz. With 14 Figures in the Text. (Leipzig: W. Engelmann, 1890.)

MINERALOGY, at first purely descriptive, has been raised to the dignity of an experimental science by the application of the principles of chemistry and physics. The writer of a mineralogical text-book is thus met at the outset with the difficulty of deciding what amount of knowledge of chemistry and physics to assume in his reader. With regard to the chemical side at least, the rule appears to be to assume that he knows very little, and yet, somewhat inconsistently, to make the exposition of the atomic theory and the fundamental principles of chemistry so brief as to be of little service to one who has had no previous acquaintance with the subject.

The author of the present, in many respects useful and suggestive, book follows the same lines. The whole account of the fundamental chemical theories occupies about ten pages of the introduction. The same fault will be found in other parts of the book: *e.g.* it would be difficult to say to what class of reader a large portion of the chapter on chemical analysis would be useful. In his endeavour to introduce as many extracts as possible from the current literature of the subject, the author allows himself in many places to become somewhat sketchy. In spite of this, the book, with its wealth of information upon points which have not hitherto found a place in ordinary mineralogical text-books, will be found to give a very good idea of the present state of mineralogical science from a chemical point of view.

The arrangement of the book is in seven sections, viz. (1) introduction; (2) chemical crystallography; (3) chemical analysis of minerals; (4) synthesis of minerals; (5) metamorphism of minerals; (6) formation of minerals in nature; (7) chemical composition and constitution of minerals.

In the introduction, containing an account of the atomic theory and its consequences, one or two suggestive ideas will be found: *e.g.* the correspondence, pointed out by Tschermak, between the chemical law of multiple proportions and the crystallographic law of simple parameter ratios; and also the analogy between the law of constant proportion by weight and the fundamental crystallographic law of constancy of angle. The subject of chemical crystallography receives very full treatment. Here the reader is initiated into the mysteries of chemical and physical isomerism, polymorphism, enantiotropy, isomorphism, isodimorphism, isogonism, morphotropy, &c.; and if the perusal of this section, as well as of the last, on the constitution of minerals, shall leave him with a rather confused and unfavourable idea of the subject, the fault should perhaps be rather attributed to the present imperfect state of our knowledge than to the author. At present it is in most cases impossible to say whether bodies are polymeric, metameric, or chemical isomers.

As regards isomorphism, if the formation of mixed crystals is to remain the test, the original definition of Mitscherlich must be modified to suit the fact of the formation of mixed crystals from compounds of not precisely analogous chemical composition. Thus, according to modern views, isomorphism is in some degree to be deposed from its proud position as an infallible guide to chemical composition. The insidious nature of the attack upon this ancient stronghold of the faith may be judged by a comparison of one of the latest definitions of isomorphism with the original definition of Mitscherlich. According to the latter, isomorphism is the power which two or more compounds of *analogous* chemical composition possess of crystallizing in the same or similar crystalline forms, and of mixing in varying proportions to form homogeneous crystals. The latest definition is that bodies are isomorphous which, with *for the most part similar* chemical composition, possess the property of crystallizing in similar crystalline forms, and of forming mixed crystals which morphologically and physically graduate into each other. Such a change it is expected would lead to a considerable simplification in many of the formulæ which have been made unnecessarily complicated in order to comply with the requirements of Mitscherlich's definition.

The section on chemical analysis of minerals is one of the least satisfactory in the book. Short summaries of analytical methods can be of little service to any class of reader. Amongst matter which will not be generally found in the ordinary chemical text-book, this section contains some account of microchemical reactions, of the methods for the mechanical separation of minerals, so as to insure pure material for analysis, and directions for the course of analysis to be pursued in the case of the more important minerals.

The important subject of mineral synthesis receives more complete treatment than any other in the book. The section contains general accounts of the various methods for the artificial production of minerals by chemical reactions, fusion, sublimation, electrolysis, diffusion, &c., with detailed descriptions of the apparatus required.

The sections on the metamorphism of minerals, and on the formation of minerals in nature, will be found of great interest to the petrologist. Here are described the effects on minerals of heat, of gases at high temperatures, of fusion, of fused magmas, of water containing carbonic acid, &c. In the last section, dealing with the composition and constitution of minerals, the present imperfect state of our knowledge is brought prominently to light. The battle is still being fought between the so-called chemical, liquid, and crystal molecule; between constitutional and empirical formulæ. Mineralogists are beginning to understand that it is impracticable to attempt to use for complicated minerals principles which are only applicable to volatile organic compounds, and the idea is gaining ground that many minerals are molecular compounds only capable of existing in the solid state, the crystal molecule being built up of different chemical molecules.

The author intends to supplement the present work by another, entitled "Chemical Mineralogy," in which the composition, synthesis, &c., of each individual mineral will be treated more particularly. The present volume is intended as quite a general treatise on the subject of mineral chemistry; in fact, we cannot help thinking that in many parts the treatment is far too general, and that the book has been partially sacrificed for the sake of the volume that is to follow. The value of the book is increased by the lists of references to the literature which precede each section. G. T. P.

OUR BOOK SHELF.

Bush Friends in Tasmania: Native Flowers, Fruits, and Insects, drawn from Nature, with Prose Descriptions and Illustrations in Verse. By Louisa A. Meredith. Executed by Vincent Brooks, Day, and Son. (London and New York: Macmillan and Co., 1891.)

UPWARDS of thirty years ago Mrs. Meredith gave the world a volume containing admirable coloured figures of a selection from the many beautiful plants and insects that inhabit her island home, Tasmania; and now, in the evening of a long life, she has travelled to the old country to publish a second volume, which is to be the last. Her purpose achieved, she "hopes to return and end her days among her children in that pleasant colony," which has given a brighter home to so many of our kith and kin. Lovers of the beauties of Nature in this country will find much pleasure and instruction in this second volume from that talented lady's pen and pencil, and will be able thereby to form some conception of the totally different kind of vegetation from our own that clothes this remote southern island, as well as the great Australian country, for it is only a part of the same flora. To the colonists themselves the book will be even more attractive, as a means of becoming acquainted with the names and affinities of the beautiful objects with which they are surrounded. It will also, it is to be hoped, teach them to prize and preserve these rare and precious gifts. Like all true lovers of Nature, Mrs. Meredith deplores the wanton destruction of rare flowers near Hobart by thoughtless or greedy persons whose only aim seems to be quantity.

The botanical part of Mrs. Meredith's book is perfectly trustworthy, having been scrutinized by so eminent an authority as Sir Joseph Hooker; and Prof. Westwood furnished the names of the insects.

Some of the poems have a special interest in connection with the early history of the settlement of Tasmania. Notably an "Old Story" of 1834, which narrates the massacre by aborigines of a whole family—father, mother, and seven children.

The Elementary Geometry of Conics, with a Chapter on the Line Infinity. By C. Taylor, D.D. (Cambridge: Deighton, Bell, and Co., 1891.)

DR. TAYLOR'S "Geometry of Conics" is so well known, and has met with such acceptance—this is the seventh edition, revised—that we are not called upon to give a detailed account of it. Two additions, however, claim a brief notice. A new chapter (xii.) contains "a course for beginners," in which students who prefer to take the three conics separately have a selection of articles, from the text, indicated for a first reading. Further, a set of duplicate proofs is given in outline, the completion of which is left to the reader. The other novelty (chapter xi.) is "a new treatment of the hyperbola." This is the expansion of a paper which the author read before the Association for the Improvement of Geometrical Teaching, in January 1890, and of which the President (Prof. Minchin) is reported to have said: "One thing that struck him about the paper was, that Dr. Taylor arrived at points on the curve in a very much more rapid and simple way than any he had previously known of." The author remarks that it is in accordance with the historical order to draw the asymptotes before tracing the curve, for the hyperbola seems to have been discovered from its "equation" (A.I.G.T. Report, 1890, p. 12).

It is somewhat remarkable that Dr. Taylor does not give a proof of this equation. We append one. Taking his figure on p. 103, we draw the second asymptote. Now draw PM parallel to Cp, cutting the axis in K, and the second asymptote in M: then,

$$\begin{aligned}4\text{CM} \,.\, \text{MP} = 4\text{MK} \,.\, \text{MP} &= (\text{MP} + \text{MK})^2 - (\text{MP} - \text{MK})^2 \\ &= \text{C}p^2 - \text{KP}^2 = \lambda^2(p\text{N}^2 - \text{PN}^2) \text{ (where } \lambda \text{ is a constant)} \\ &= \lambda^2(\text{S}p^2 - \text{SP}^2) \\ &= \lambda^2(\text{S}p^2 - p\text{Y}^2) = \lambda^2 \,.\, \text{SY}^2 = \text{C}a^2 = a^2 + b^2.\end{aligned}$$

Again, let PQ be any chord meeting the asymptotes in p, q; and let Ql, Pm, parallel to Cp, Cq respectively, meet those lines in l, m. Then we have

$$\frac{\text{P}q}{\text{C}m} = \frac{\text{P}p}{pm} = \frac{pq}{\text{C}p} = \frac{\text{Q}q}{\text{Q}l},$$

$$\therefore \quad \frac{\text{P}q}{\text{Q}q} = \frac{\text{C}m}{\text{Q}l} = \frac{\text{C}l}{\text{P}m} = \frac{p\text{Q}}{\text{P}p};$$

hence

$$\text{P}p = \text{Q}q, \text{ and } \text{P}q = p\text{Q}.$$

Other properties occur to us, but the above are classic properties of the curve, and the wonder is that Dr. Taylor has not applied his new treatment to obtain them. There is no suggestion that they can be so obtained, either in the book or the original paper as printed in the A.I.G.T. Report. R. T.

Les Engrais Chimiques. Par Georges Ville. Septième Édition. (Paris: M. Engel, 1890.)

THIS is a new edition of the author's lectures on chemical manures, which were first published in 1868, and which have been translated into seven languages. An English edition, by Mr. Crookes, was published in 1879. The sixth French edition has been out of print for about ten years, and during that time the price of chemical manures has considerably declined, on an average about 40 per cent. On this account the author has introduced, at the end of the volume, a chapter containing new formulæ for mixed manures, based on considerations of market value and more complete knowledge of the requirements of crops. Thus, potassium chloride replaces potassium nitrate in the manure for leguminous plants, and in some cases a mixture of potassium chloride and ammonium sulphate replaces potassium nitrate; and a few other alterations are suggested in the treatment of various crops. Thomas's basic cinder is not mentioned as a source of phosphoric acid. The lectures themselves, and some controversial matter, are reprinted in their original form, and but little new matter is added.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Bird-Collections in the Oxford University Museum.

DURING a recent visit to Oxford I took the opportunity of examining the collection of birds in the University Museum, and beg leave to offer a few remarks upon its condition.

First, as regards the mounted specimens, there are three series belonging to this category:—

(1) The general series in the Central Court. This numbers about 1100 specimens, which are contained in twelve cases, placed in opposite rows of six each, but rather mixed up with mammals, shells, and other objects. The specimens are arranged according to Gray's "Genera," and in most cases correctly named. But many of them are in bad order and not well set up, and should be replaced by fresh examples. The whole series requires renovation and rearrangement, according to some modern system, and the orders and families should be designated by labels, and distinctly separated one from another.

(2) The collection of Arctic birds formed by Mr. J. Barrow, F.R.S., and presented to the Museum by that gentleman. This interesting collection, which has been well described by Mr. Harting in the *Ibis*, is placed in the gallery. It is well mounted and correctly named. But it is a question whether it is desirable to keep it apart from the general series.

(3) The British series, also placed in the gallery, which is in fair order, although it also requires revision and rearrangement according to some modern system. It ought not to be difficult to find some member of the British Ornithologists' Union to undertake this task, provided that the authorities will allow him a "free hand."

Besides the mounted specimens, there are, as I understand, about 4000 skins of birds, most of which are "put away" in boxes in various parts of the building. Of these, the only portion that I was able to see was the Bornean collection formed by Mr. Everett, and partly described by Dr. Bowdler Sharpe in the Zoological Society's Proceedings. These are placed in some drawers in the main hall. The other skins are stated to be "boxed up," and are kept partly in a room on the ground floor, and partly in some "upper chamber," to which no ready access is possible.

I venture to suggest that one of the side rooms in the Museum should be cleared of its contents, and devoted entirely to the bird-skins, and that they should be arranged there in cabinets, so as to be accessible to the ornithologist. It is hardly right for a great and rich University to accept collections from persons who, in the words of the late Prince Bonaparte put forward on a similar occasion, "croyant qu'ils travaillaient pour la science, non pas travaillés que pour les mites." I may add that any assistance that I can give in carrying out this reform will be most gladly rendered. P. L. SCLATER.

3 Hanover Square, London, W., September 4.

Variation and Natural Selection.

IN Prof. C. Lloyd Morgan's Presidential address to the Bristol Naturalists' Society, on "The Nature and Origin of Variations" (of which he has kindly sent me a reprint from the Society's Proceedings), there are one or two points on which there seems to me to be a slight misconception; and as the difficulties suggested have probably occurred to other naturalists, I wish to make a few observations in the hope of throwing a little light on this obscure subject.

After referring to the proofs of the variability of species in a state of nature which I have adduced in my "Darwinism" (to which proofs Prof. Lloyd Morgan has made some important additions in his recent work on "Animal Life and Intelligence") he remarks:—"We have been apt to suppose that a species is so nicely adjusted to its surrounding conditions that all variations from the type, unless of a very insignificant character, would be rapidly and inevitably weeded out. This, it is clear, is not true at any rate for some species." And a little further on, after discussing the question whether variations in all directions occur in equal proportions—an equality which does not appear to me to be at all necessary, or to have been ever suggested as occurring—he says: "And the candid biologist must, I think, admit that the evidence in Mr. Wallace's third chapter, while conclusive as to the occurrence of variations, gives on analysis little or no evidence of any selective agency at work."

The difficulties here stated appear to me to depend, chiefly, on not taking account of some important facts in nature. The first fact is, that the struggle for existence is intermittent in character, and only reaches a maximum at considerable intervals, which may be measured by tens of years or by centuries. The average number of the individuals of any species which reach maturity may be able to survive for some years in ordinary seasons or under ordinary attacks of enemies, but when exceptional periods of cold or drought or wet occur, with a corresponding scarcity of certain kinds of food, or greater persecution from certain enemies, then a rigid selection comes into play, and all those individuals which vary too far from the mean standard of efficiency are destroyed.

Another important consideration is that these epochs of severe struggle will not be all of a like nature, and thus only one particular kind of unbalanced or injurious variation may be eliminated by each of them. Hence it may be that for considerable periods almost all the individuals that reach maturity may be able to survive, even though they exhibit large variations in many directions from the central type of the species. During such quiescent periods, the chief elimination will be among the young and immature. Thus, with birds probably nine-tenths of the destruction occurs among the eggs and half-fledged young, or among those which have just escaped from parental care; while those which have survived to breeding age only suffer a slight destruction in ordinary years, and this may occur partly among the less experienced, partly among those which are old and somewhat feeble.

The severe elimination that occurs in the earlier stages may be thought to be accidental, but I doubt if it is really so except in a very small degree. The protection and concealment of the eggs and young in the nest will depend chiefly on the mental qualities or instincts of the parents, and these will have been always subject to a rigid selection owing to the fact that those with deficient instincts will leave fewer offspring to inherit their deficiency. And with young birds of the first year there will be an equally rigid selection of the incautious, and of those who are deficient in any of the sense-perceptions, or are less strong and active than their fellows.

The proof that there *is* a selective agency at work is, I think, to be found in the general stability of species during the period of human observation, notwithstanding the large amount of variability that has been proved to exist. If there were no selection constantly going on, why should it happen that the *kind* of variations that occur so frequently under domestication never maintain themselves in a state of nature? Examples of this class are white blackbirds or pigeons, black sheep, and unsymmetrically marked animals generally. These occur not unfrequently, as well as such sports as six-toed or stump-tailed cats, and they all persist and even increase under domestication, but never in a state of nature; and there seems no reason for this but that in the latter case they are quickly eliminated through the struggle for existence—that is, by natural selection.

One more point I will advert to is Prof. Lloyd Morgan's doubt, in opposition to Mr. Ball, "whether a thicker or thinner sole to the foot is a character of elimination value, whether it would determine survival or elimination, and make all the difference between passing or being plucked in life's great competitive examination." This seems to me to be a rather unfortunate objection, since, in constantly recurring circumstances during the life of a savage, this very character must be of vital importance. Whether on the war-path, or in pursuit of game, or when escaping from a human enemy or from a dangerous animal, the thickness of the sole, its insensibility to pain, and its resistance to wear and tear must have often determined life or death. A man who became sore-footed after a long day's tramp, or one whose thin sole was easily cut or torn by stones or stumps, could never compete with his thicker soled companions, other things being equal; and it seems to me that it would be difficult to choose a single physical character whose variations would be more clearly subject to the law of selection.

With the greater portion of Prof. Lloyd Morgan's very interesting address I am in perfect accord, and it is because his remarks and suggestions are usually so acute and so well founded that I have thought it advisable to point out where I think that his objections have a less stable foundation.

Alfred R. Wallace.

A Rare Phenomenon.

The rare phenomenon to which your two correspondents refer in their letters in your last issue (p. 494) was visible here at precisely the same time, and, viewed from Nottingham Forest, it presented a most interesting sight. It is curious that, as both the time and duration of the phenomenon coincide with its appearance here, its characteristics should be so dissimilar. It had more the appearance of a well-defined display of the aurora. Rays of light springing from the horizon penetrated high into the heavens, lasting about 10 or 15 seconds, and then disappeared, others taking their places. Its centre appeared to me to be almost due north, and, from notes made at the time, the beams or luminous rays reached an angle of about 50°, stars being visible through them. There was no arc visible of the character described by your correspondents, but vertical changing rays, several of which were distinctly orange-tinted.

Nottingham, September 26. Arthur Marshall.

Your columns record, from Ireland and Scotland, observations of the aurora to which I called attention last week. It was seen also in Warwickshire, the coruscations being so marked as to remind my informant of the search-light at the Naval Exhibition. Mr. E. B. Knobel informs me that, from 8 to 10 p.m. on the 11th, during which time the appearance was visible, active magnetic disturbances were noticed at the Royal Observatory, Greenwich, illustrating the close connection which has been established between auroral and magnetic phenomena.

W. Tuckwell.

It may be of interest to your readers to know that the "rare phenomenon" mentioned (p. 494) was seen by me from Ryde, I.W., on Friday, the 11th. A streak of light (at first thought to be a ray proceeding from a search-light), was visible near the Pleiades, at about 9.30, extending over an arc of about 45°, the width being probably about 1°. It gradually faded away, and at 10 no trace of it was left. F. C. Levander.

30 North Villas, Camden Square, N.W., September 28.

Instruments in Just Intonation.

As you have raised once more the question of justly intoned instruments, may I offer the following remarks? It does not seem likely that any arrangement for the organ would be practically adopted unless it permits as much freedom of modulation and of execution as that of equal temperament. To permit perfectly free modulation, with practically perfect intervals, nothing short of the cycle of fifty-three will suffice. Now to construct a key-board with fifty-three notes to the octave which can be played upon with the facility of a twelve-note key-board seems impossible. But the problem may be approached differently: as it is only necessary to use twelve notes at a time, the key-board might remain as it is, and only a mechanical device would be required to make these twelve keys correspond to the right twelve out of fifty-three pipes; if the services of an assistant be allowed (as is often necessary on large organs) the mechanical difficulties could easily be overcome. For example, arrange a number of studs—say 117, as suggested by Dr. Ellis—as a "duodenarium," and connected electrically to the fifty-three trackers; *i.e.* each tracker would be connected to two or three studs—$B^3\flat\flat$, $C^4\flat\flat\flat$, $A_3\sharp$ studs to tracker 46 for instance. Opposite these studs would be another set of 117 connected to the twelve keys, *e.g.* C, $B_2\sharp$, $B_3\sharp$, $D^2\flat\flat$, &c., all to the key C. Between the two sets of studs would be a frame carrying twelve contact pieces; the frame would then be moved along guides by the assistant, so that the twelve keys were electrically connected to the right duodene of studs, and hence could be made to open the right group of pipes.

Thus the only alteration in printing required would be to mark the duodene on the music. All the extra complication would be thrown on the mechanical arrangements, and the organist would be left in the same position as now. It seems to me that any more complicated key-board would fail in a large organ, through overburdening the organist.

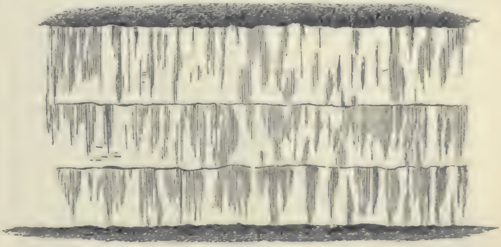
Firth College, Sheffield, September 14.

Unusual Frost Phenomenon.

The following is extracted from a letter dated Dubbo Creek, near Tumut, New South Wales, July 26, 1891:—

"I noticed the other day a strange effect caused by the late very hard frosts. It was a peculiar upheaval of the crust of the ground by a mass of innumerable threads of ice taking the form of spun glass or fine asbestos fibre. There were five layers of this ice-fibre, the uppermost bearing the raised earth-crust. Every night's frost was shown by its distinctive layer of fibres.

"As perhaps you may never have seen this form of ground frost, I append a rough sketch of its very singular appearance.



I have only shown three layers; there were five, but this may give you some idea of its appearance—quite a columnar basaltic appearance.

"Every morning here after a sharp frost, the whole of the ground, where not covered by grass or rubbish, is raised up thus. On the sides of the cuttings and banks of our claim, these ice-fibres may be seen projecting from the walls in bunches of snowy filaments, like spun glass. The sun, however, soon causes them to drop off, and they lie in heaps of some six inches in depth." A. H. White.

Richmond, Surrey.

The Destruction of Mosquitoes.

On two occasions, when proceeding northwards to Arctic Norway, I was much interested in observing the fact that the plague of mosquitoes, which is so intolerable there, especially prevails in latitudes beyond the northern range of the swallow.

This may possibly be a mere coincidence, but I think it is not—an opinion strongly supported by another and very broad fact, viz. that in a given district in our own country the gnats become more abundant immediately after the departure of the swallows, martins, &c. If this view is correct, the protection of these birds should be added to the devices named in your review of "Dragon-flies *v.* Mosquitoes." Such protection is very different from the indiscriminate sentimentalism about "small birds" which breaks out periodically at this season in the newspapers, and includes such feathered vermin as the thick-billed, seed-grubbing, pea-shelling, graminivorous sparrow among the objects of its tenderness. W. Mattieu Williams.

The Grange, Neasden, N.W.

A Tortoise inclosed in Ice.

DURING the last winter there was a good deal of correspondence in the columns of NATURE regarding the revivability of fish and insects that had been frozen hard. A similar phenomenon with regard to the tortoise having recently come under my notice, it may perhaps be interesting to some of your readers to have it put on record.

Some friends of mine have one of the small water-tortoises that are occasionally exposed for sale in the City. Last winter, this tortoise was inadvertently left in his small pond, the water of which froze completely into one block of ice, inclosing the tortoise. When the thaw came, the creature was found alive and flourishing. I especially endeavoured to ascertain whether the tortoise had been absolutely and completely *inclosed* in his icy casing, or whether he had been simply frozen into the ice, but partly inclosed and partly free. Unfortunately, however, in spite of cross-examining several of the family, I was unable to obtain a perfectly clear and definite statement on this point: one of my friends, however, declared that, if not completely encased, at any rate only the arch of the tortoise's back was free. This is, however, sufficiently indefinite to debar one from asserting that all access of air was denied to the tortoise; and that is the point on which my interest chiefly centred.

The Soaring of Birds.

I HAVE read with much interest Mr. Peal's account of the soaring of vultures, pelicans, adjutants, &c., over the plain of Upper Assam (NATURE, May 21, p.56). Their manner of flight is identical with that of seagulls and harriers over the Canterbury Plains in New Zealand, which is about 150 miles long and 45 wide in its widest part. These birds begin to soar at a height of about 200 feet, and rise in slanting spirals to 2000 feet and under. The gulls are much the most numerous, and flocks of them may be seen soaring nearly every fine day in summer. Sometimes a number assemble, and after going round in circles for a short time, without rising, or rising very little, they come down, the condition of the air being apparently unfavourable for soaring. Whenever I have seen a flock finish an ascent, they all reached the same height, which is consistent with the supposition that they go as high as they can. They never remained at the limit of their ascent even for a short time, but separated, sailing away downward to great distances.

The explanation of soaring given by Mr. Peal can hardly be the true one. Bishop Courtenay has shown its inadequacy by proving that a bird in a uniform horizontal current is in no respect more able to support himself than in a calm. Though carefully looking for it, I have never been able to see the descent which Mr. Peal supposes to be made (he does not say that he has seen it) when the bird is going with the wind.

The soaring of birds shows plainly that the velocity of the wind over a flat country does not increase with the height in a perceptible degree up to great heights. If there were such an increase at anything like the rate near the ground, a bird soaring would be out of sight long before he could reach 1000 feet, but birds seem to drift horizontally at nearly the same speed during the whole of their ascent. The increase of the velocity of the wind with the height may be studied by observing the behaviour of smoke or steam carried along: near the ground the increase is easily seen, over 20 feet it is very small, over 50 seldom perceptible, a wreath of smoke over that height being carried along without any relative motion of the parts, or so little that it could be of no use in soaring.

In a description of the sailing flight of the albatross (NATURE, vol. xl., p. 9) I mentioned that when the wind is at right angles to the course of a steamer attended by a flock of albatrosses, some of them occasionally follow the vessel not far astern in undulating lines, rising against the wind and falling with it, and turning alternately right and left; also that seagulls do an imperfect imitation of this kind of flight over flat country, nearly touching the ground at each descent, as the albatrosses nearly touch the sea. The gulls are evidently unable to reach the height from which the previous descent was made without flapping their wings a few times during the second half of each ascent. Without doing this, they would soon come to the ground, though using the differential motion of the air, where it is at its maximum, to the greatest advantage possible. It seems, therefore, that soaring at great heights cannot be explained on the same principle as the sailing flight of the albatross, whose movements are confined to a comparatively thin stratum of air next the sea, in which the velocity of the wind increases rapidly with the height.

In Lyttelton Harbour, N.Z., which is surrounded by hills except at the entrance, the gulls soar by using the upward current on the slopes, rising in spirals in precisely the same manner as when soaring hundreds of feet above the plain. The motive power in the former kind of flight is evident, and perhaps throws light on that of the latter. Standing on a slope of about 20°, and about 100 feet above the sea, I saw a flock of gulls sitting on the water. A breeze sprang up, and the whole flock began to ascend over the slope. Being constantly among the shipping they are very tame, and several came within 12 feet of me. When moving against the wind their motion with respect to the earth was very slow, so that I had a good opportunity of seeing if there was any vibratory movement of the wings, but no movement of any kind was visible. The ascent of birds over a slope by means of the current flowing up it, and their descent in long inclines at a small angle with the horizontal, show that rapid motion through the air causes a great resistance in opposition to gravitation, which resistance has not yet, I believe, been accounted for quantitatively on mechanical principles.

The explanation of soaring at great heights which presents the fewest difficulties seems to me to be—that it is done by means of upward currents. This has been suggested by several observers, its main difficulty being the uncertainty that there are such currents of sufficient strength. I shall try to show that upward currents may be caused in two ways, but it would not be possible to give a direct proof that the currents so arising are strong enough. If, however, birds are seen to soar when one or other of these causes is present, there is a strong probability that they are true causes of soaring.

Everyone who has watched the working of a windmill must have seen that the force of the wind varies frequently, and sometimes rather suddenly. It is evident that there must be an ascent of air in front of a current moving faster than the average speed, and a descent of air behind it. As an example of this, a cold south-west wind was blowing, with showers of rain at intervals, accompanied, as often happens, by increased force of the wind. I saw a flock of gulls soaring in front of one of these squalls. There can, I think, be little doubt that there was an ascending current, of which the gulls took advantage.

Mr. W. Ferrel has shown ("Popular Treatise on the Winds") that if the rate of fall of temperature with increase of height be greater than the rate of dynamical cooling of an ascending current, the atmosphere is in an unstable state—that is, if by any cause a mass of air be started in an upward direction in such an atmosphere, the density of the ascending air is less than that of the surrounding still air, so that the former would be driven upwards, and an ascending current established, which would tend to rush up to the top of the atmosphere if the instability, consequent on the vertical decrease of temperature, should extend all the way up; but if the instability did not extend to the top, then, at its limit, the impelling force would cease, and friction would soon bring the ascending current to rest. Conversely, in an unstable atmosphere, if a mass of air be started downward, the density of the descending air is greater than that of the surrounding still air, and the descent tends to continue down to the ground. Mr. Ferrel says (p. 440):—"The unstable state in unsaturated air occurs mostly on very dry and sandy soils with little heat conductivity, when the weather is very warm, and the heat rays of the sun are unobstructed by any clouds above. The heat thus accumulates in the surface strata of the soil and the lower strata of the atmosphere, and thus is brought about the unstable state, at least up to a low altitude, even in clear dry weather." And in speaking of what may be called a multiple tornado (p. 412): "As the tornado originates in air in the unstable state, it often happens that there is about an equal tendency in the air of the lower stratum to burst up through those above at several places in the same vicinity at the same time."

This tendency of the lower strata to burst up in separate spots may exist where the instability is much less than that required to cause a tornado, as in the case of a plain strongly heated by the sun, and in the absence of any gyratory motion round the centre of an ascending current, there would be no whirlwind, only a quiet ascent of air, in a slanting direction if there were any wind. Such ascending currents may be of small area, not much larger than the circles described by birds when soaring. It seems possible that the object of describing circles may be to keep within the ascending current, though it is true they sometimes describe circles when the ascending current is up a slope and not limited to a small area. If a plain much heated by the sun border on the sea, ascending currents will soon start a sea-breeze, and the cold air from the sea will soon restore the stability of the atmosphere. In summer the sea-breeze blows over the Canterbury Plains four or five days a week, beginning between 8 a.m. and noon. When delayed till near noon, the soil and lower strata of air are much heated, and as the previous nights are cool, the conditions for causing the unstable state are present. I long ago remarked that the best time to look out for soaring birds is at the commencement of the sea-breeze when it is late. Soaring is much oftener seen here in summer than in winter, and is, I believe, more common, and the species of soaring birds more numerous, and the birds larger, in hot than in cold climates—that is, in climates where the unstable state of the atmosphere is oftenest caused by the sun's heat.

Mr. Peal says: "That there are no uprushes of air I have fairly good proof in the small tufts of cotton from the *Bombyx malabaricum* which cross the field of my telescope when examining the Noga Hills at ten, twenty, or thirty miles; these are always beautifully horizontal at elevations of from 200 to 2000 feet, coming from the plains and hills to the north-east of us." The presence of light bodies at great heights seems to show that there *are* upward currents: no doubt uprushes of air at a large angle with the horizontal, and of considerable area, might be detected by a careful observer from the movements of small floating bodies, but upward slanting currents of small area might easily escape observation.

It is obvious that upward currents over a plain, caused either by variations in the velocity of the wind or by the unstable state of the atmosphere, must be almost insensible near the ground, and could not attain their full strength under a considerable height. This accounts for the fact that over plains birds do not begin to soar at less than about 200 feet. If soaring were possible in a uniform horizontal current, they would save themselves the muscular effort of rising 200 feet and over by the active use of the wings, and would begin to soar immediately on leaving the ground, as they do in currents blowing up a slope.

I have often observed gulls with extended motionless wings following a steamer in the same relative position for several minutes. In every case it was clear that they used the current diverted upwards by the hull. Before the upward energy of this current is exhausted, a fast steamer has gone a good many yards, so that a bird is supported at some distance astern. Also an upward current of considerable strength would flow off the mizen sail of a ship sailing near the wind and leaning over.

Christchurch, N.Z. A. C. Baines.

Rain-making in Florida in the Fifties.

The article on "Rain-making in Texas" (Nature, p. 473) recalled to my memory a passage of Dr. Th. Reye's book ("Wirbelstürme, Tornados, &c.," Hanover, 1872), in which (at p. 12 and following) the author in question translates quotations from J. P. Espy's "Second and Third Report on Meteorology, 1851, auf Befehl des Senates der Union gedrukt" (Reye's note at his p. 235; quoting also fourth Report, 1857). The facts related were observed by the surveying officers George and Alexander Mackay. They (in Florida) had at their disposal great quantities of rushes (saw-grass), which they set in flame, and the huge conflagrations were invariably followed by rain.

A Dog Story.

The following dog story may interest your readers.

As I went to the train one morning, I saw a brown retriever dog coming full speed with a letter in his mouth. He went straight to the mural letter box. The postman had just cleared the box, and was about 20 or 30 yards off when the dog arrived. Seeing him, the sagacious animal went after him, and had the letter transferred to the bag. He then walked home quietly.

Putney, September 23. John Bell.

SOME NOTES ON THE FRANKFORT INTERNATIONAL ELECTRICAL EXHIBITION.[1]

II.

A Page of Modern History.

Electric transmission of power to great distances bids fair in the near future to change the whole commerce of the world, and yet the history of its development is all comprised within the last fourteen years. In a long paper read in the early part of 1877 before the Institution of Civil Engineers, "On the Transmission of Power to a Distance," the author, Prof. Henry Robinson (now the engineer to various electrical companies), does not even suggest the possibility of employing electricity for this purpose. So that in the discussion Sir William Siemens remarked, "He might also refer to another method of transmitting power to a distance, which did not seem to have occurred to the author, perhaps because it was of recent date, viz. by electric conductors."

A week later, Sir W. Siemens, in his Presidential address to the Iron and Steel Institute, throws out the idea of utilizing the power wasted in the Falls of Niagara; and after referring to the use of high-pressure water mains and quick-working steel ropes for transmitting power over one or two miles, he says, "Time will probably reveal to us effectual means of carrying power to great distances, but I cannot refrain from alluding to one which is, in my opinion, worthy of consideration—namely, the electrical conductor." And he adds, "A copper rod three inches in diameter would be capable of transmitting 1000 horse-power at a distance of, say, thirty miles."

The use of the electric current for the transmission of power over considerable distances was, therefore, fully present in the mind of Sir William Siemens in 1877, but not apparently the employment of the high potential differences which are absolutely necessary to make such a transmission commercially possible. For a copper rod of three inches diameter, such as he speaks of, has a cross-section of nearly seven square inches, and could carry some 5000 or 6000 amperes without undue heating. Therefore, even when the problem of transmitting 1000 horse-power over thirty miles was in question, he did not contemplate, apparently, using a pressure of more than about 100 volts.

At the commencement of the following year, 1878, in his Presidential address to the Society of Telegraph Engineers, he refers to his previous statement, and adds, "Experiments have since been made with a view to ascertain the percentage of power that may be utilized at a distance." The result obtained, he says, is that "over 40 per cent. of power expended at the distant place may be recovered"; but Sir William adds, in reference to the 60 per cent. loss, "This amount of loss seems considerable, and would be still greater if the conductor through which the power were transmitted were of great length."

The length of the conductor employed in the above experiment is not given, but its approximate length, as well as what is understood by "great length," may be gathered from the context; for Sir William goes on to consider the problem "of distributing the power of a steam-engine of, say, 100 horse-power to twenty stations within a circle of a mile diameter"; and although the distance to which it is proposed to transmit the power is only one mile, he assumes that the loss is what was found in the above experiment, viz. 60 per cent. He further adds, "The size of the conductor necessary to convey the effect produced at each station need not exceed half an inch in external diameter." Clearly, then, as the power proposed to be transmitted by the half-inch conductor to each station one mile distant was only 5 horse, there was no idea of using a potential difference in the transmission higher than that maintained between the terminals of a lamp.

---

[1] Continued from p. 497.

Two wrong notions misled people in those days—the one, that the maximum efficiency of a perfect electromotor could be only 50 per cent.; the other, quoting the remarks of Sir W. Siemens in the discussion of the paper read by Messrs. Higgs and Brittle at the Institution of Civil Engineers somewhat later in the same year 1878, "In order to get the best effect out of a dynamo-electric machine there should be an external resistance not exceeding the resistance of the wire in the machine. Hitherto it had been found not economical to increase the resistance in the machine to more than one ohm; otherwise there was a loss of current through the heating of the coil. If, therefore, there was a machine with one ohm resistance, there ought to be a conductor transmitting the power either to the light or the electromagnetic engine not exceeding one ohm." He then goes on to consider that as the conductor is lengthened its cross-section must be increased in proportion to keep the resistance constant at one ohm; and he arrives at a result quite new at the time, viz. that if the number of dynamos *in parallel* were increased in proportion to the length and cross-section of the line, "it was no dearer to transmit electromotive force to the greater than to the smaller distance."

Sir William Thomson grasps at once the novelty and importance of this idea, and renders it even more important by proposing to put all the dynamos *in series* at one end of the line, and all the lamps in series at the other. But it would still appear that even 40 per cent. efficiency for transmision over a considerable distance could only be attained when "there were a sufficient number of lamps" to make it necessary to use *many* dynamos in parallel in accordance with Siemens's proposal, or, *many* dynamos in series in accordance with Thomson's modification of Siemens's proposal.

In 1879, the electric transmission of power was still such a *terra incognita* that the largest firm of electrical engineers in Europe could not be induced to tender for transmitting power over ten miles in India.

At the British Association lecture in the autumn of 1879, Prof. Ayrton exposed the fallacy of assuming that 50 per cent. was the maximum efficiency theoretically obtainable with an electromotor. He further proposed that, instead of employing many dynamos at one end of the line and many lamps at the other, there should be used a single dynamo and a single motor, with much wire on each; that the high potential of the line necessary for economical transmission of power should be maintained by running both dynamo and motor much faster than hitherto; and that both dynamo and motor should be separately excited. Although not wholly free from the prevailing idea of that day—that electric transmission of power over long distances would only be commercially possible when a very large amount of power had to be transmitted—he says, after discussing the subject, "So now we may conclude that the most efficient way to transfer energy electrically is to use a generator producing a high electromotive force and a motor producing a return high electromotive force; and by so doing the waste of power in the transmission ought, I consider, to be able to be diminished with our best existing dynamo-electric machines to about 30 per cent."

This was perhaps the first time that it had been even suggested that the efficiency in electric transmission of power could be more than 50 per cent.

Further, the lecturer proposed to use in all cases this high E.M.F. motor, whether the received power were required for motive purposes, for light, or for electroplating; and, as experimentally shown in the lecture, to generate the current locally in the two latter cases by using the motor to drive a suitable dynamo, thus giving the first illustration of the employment of an electric transformer in the actual transmission of power to a distance.

Two years later, viz. in 1881, the old mistaken notion, that it was only 50 per cent. of the power given to a dynamo that could be returned by the motor, was again propounded during a discussion at the Society of Arts; and the Chairman, Sir W. Siemens, when correcting the speaker's error, added, "Experiments of undoubted accuracy had shown that you could obtain 60 or 70 per cent."

In this year two very important propositions were put forward—the one, by Sir W. Thomson, at the semi-centenary meeting of the British Association, that, in the electric transmission of power, the small current of high potential difference should be employed at the receiving end of the line to charge a large number of accumulators in series, the accumulators being subsequently discharged in parallel for supplying light or power to a town; the other, by MM. Deprez and Carpentier, to use one alternate current transformer at the sending end to raise the electric pressure, and another transformer at the receiving end to lower it down again, the arrangement being symbolically shown in Fig. 1.

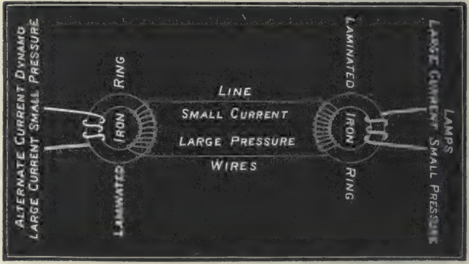

FIG. 1.—Deprez and Carpentier's Plan of Double Transformation.

The great advantage of this combination is, that the pressure along the line may be very high, and the line therefore composed of only thin wire, whereas the pressure between the leads from the generating dynamo at the transmitting end, as well as the pressure between the lamp mains at the receiving end of the line, may be as low as if the dynamo and lamps were close together.

In the experiments, however, made in the following year, 1882, to transmit power from Miesbach to Munich, along thirty-five miles of iron telegraph wire 0·18 inch in diameter, the current going by one wire and returning by another, M. Deprez did not employ his double transforming arrangement described above, probably because alternate current motors were then quite untried practically. But, instead, he used a direct current dynamo generating a potential difference of some 1500 volts, the current from which set in motion a direct current motor, wound to stand a similar high pressure, placed at the other end of the telegraph line.

The experiments were attended with various breakdowns of the dynamo, which was probably constructed on the usual string-and-glue fashion of those days; and finally, after repairs had been effected, the power given out by the motor at Munich was only a fraction of 1 horse, with a commercial efficiency of about one-third.

It was, therefore, decided to repeat the experiments the next year, 1883, with machines constructed more solidly, and for the convenience of the jury the dynamo and motor were placed close together in the workshops of the Northern Railway near Paris, one terminal of each being connected by a short wire, and the other terminals by a telegraph wire 0·157 inch thick going from Paris to Bourget and back again, a distance of 18,133 yards. The power used in driving the dynamo was towards the end of this second set of experiments about 10½ horse, and the power given out by the motor about 3⅓ horse, the potential difference at the dynamo terminals being some 1850 volts.

The arrangement of the machines was very bitterly criticized: some pronounced the result a great success; others that the whole thing was a fraud, that the power did not go from the dynamo at Paris to Bourget and back again, but that, owing to leakage from one of the telegraph lines to the other, the actual distance over which the power was transmitted was far less than the distance stated.

The next experiments were made with the same machines rewound and improved in insulation. They were now employed to transmit power over 8¾ miles, from Vizille to Grenoble, a pair of silicium bronze wires 0·079 inch in diameter being used to connect the dynamo and motor. A difference of potential of about 3000 volts was employed, and 7 horse-power was given off by the motor with a commercial efficiency of 62 per cent.

This experiment of transmitting power from Vizille to Grenoble in 1883 was distinctly successful, and constituted a great advance on anything in electric transmission that had been attempted before. It is interesting, for example, to compare it with the transmission from Hirschau to Munich by Mr. Schuckert in 1882, and which was regarded as very striking at the time it was carried out.

Transmission of Power.

	1882. Hirschau to Munich.	1883. Vizille to Grenoble.
Distance in miles ...	3½	8¾
Diameter of conducting wire in inches ...	0·18	0·079
Horse-power delivered by electromotor ...	5·8	7
Commercial efficiency of the transmission...	36	62
Potential difference at terminals of dynamo in volts	700	3000

Comparing, then, the Vizille transmission of 1883 with the Hirschau transmission of 1882, we see that the distance was twice as great, the cross-section of the wire less than one-quarter, the power somewhat greater, and the efficiency nearly twice as great; this great improvement being effected by using a pressure of 3000 instead of 700 volts.

But with 3000 volts the limit of constructing the commutator of an ordinary direct current dynamo or motor is reached—a fact which was not appreciated by M. Deprez. For when it was decided somewhat later to try and transmit 200 horse-power through 35 miles of copper wire 0·2 inch in diameter, stretched on telegraph poles between Creil and Paris, by using a pressure of 6000 or more volts, the same system of *direct* current dynamo and motor, that had been employed by M. Deprez in his previous transmissions, was resorted to. The result was that the 200 horse-power had to be reduced to 100, and the dynamo and motor were burnt up time after time.

Eventually, after the expenditure of a very large sum of money, spent in several rewindings of the machines, &c., M. Deprez succeeded in 1886 in obtaining from the shaft of the motor at Paris 52 horse-power, this being 45 per cent. of the power spent in driving the dynamo at Creil. The power delivered at Paris was distributed by coupling a low potential difference dynamo to this motor, and using the current developed by this dynamo for driving various smaller motors, so that the power actually delivered to the pumps, &c., was somewhat less than the 52 horse stated above.

In the use of a dynamo and motor each with a high resistance armature and a low resistance field magnet, the fields being produced by separate excitation, and in the employment of a motor-dynamo for utilizing the received power, M. Deprez expressed his approval of the very plan proposed by Profs. Ayrton and Perry in 1879 for "sending by even quite a fine wire a small current," and so obtaining "an economic arrangement for the transmission of power."

This experiment, although very costly, had considerable interest, in showing that as much as 52 horse-power could be actually delivered at the end of thirty-five miles of copper wire 0·2 inch thick, and that a pressure of 6000 volts could be practically employed with a lead covered insulated conductor. But probably the most important lesson learned from it was, that when the distance over which power had to be transmitted was so great that a pressure of 6000 volts became necessary to obtain economy in the conducting wire, an alternating and not a direct current ought to be used.

While these various experiments of M. Deprez with direct currents were being carried out, the transmission of power by means of alternating currents had been progressing in the face of considerable opposition. The exhibition at the Aquarium, Westminster, in the spring of 1883, will probably be chiefly remembered from its being there that Messrs. Gaulard and Gibbs showed what they called a "secondary generator," which was simply an improved form of Ruhmkorff induction coil, without the ordinary vibrating make and break. A current from an alternating dynamo was sent round one of the coils, and to the terminals of the other were attached lamps, the brightness of which could be varied by pulling out the iron core of the induction coil more or less, as is done with medical coils to alter the strength of the shocking current.

Nobody thought much of the "secondary generator"; it seemed to have no very special use; the iron core felt very hot, so that there would be a new waste of power introduced into electric lighting by the use of secondary generators. Besides, the electricians saw that Messrs. Gaulard and Gibbs were employing methods and apparatus for measuring the power which must give totally erroneous results when used with alternating currents; and so, forgetful of the fact that invention is frequently quite ignorant of the language of the text-book, they decided that there was nothing in it.

But Messrs. Gaulard and Gibbs believed in their secondary generator, whatever electricians and the technical press might say; they put them at the Notting Hill Gate, Edgware Road, Gower Street, King's Cross, and Aldgate stations of the Metropolitan Railway, joined the fine wire coils of all the generators *in series* with one another, and sent a small alternating current through the whole circuit from a dynamo placed at Edgware Road. Lamps of different kinds attached to the thick wire coils of each of the generators at the five railway stations burned steadily and brightly; an alternate current motor, even, which was put at one of the stations, revolved rapidly: but what a great waste of power there must be in all this unnecessary transformation, said the learned.

Well, in the spring of the next year, 1884, Dr. J. Hopkinson tested the efficiency of these secondary generators on the Metropolitan Railway, and, to the surprise of nearly everyone, it came out close on 90 per cent.

In the autumn of the same year, in connection with the Exhibition at Turin, power was transmitted to Lanzo, twenty-five miles away, by means of a bare overhead wire rather less than one-quarter of an inch in thickness, and, by means of Gaulard and Gibbs's secondary generators, the power was distributed at Lanzo and elsewhere along the route, for lighting incandescent and arc lamps. The jury reported that the efficiency of the transformers was 89 per cent., the whole distribution strikingly successful, and a prize of 10,000 francs was awarded to Messrs. Gaulard and Gibbs by the Italian Government.

No electromotors, however, appear to have been driven by the transmitted power, for, even in 1884, alternating current electromotors were still comparatively untried.

Tests of a secondary generator were next undertaken in 1885 by Prof. Galileo Ferraris, of Turin, who found the efficiency at full load to be no less than 97 per cent.,—a value even higher than that previously published. This investigation is the more memorable, in that it led Prof. Ferraris to take up the mathematical and experimental investigation of alternating currents, resulting in the discovery and construction of the self-starting alternate current motor in 1885, and to extensions of considerable practical importance in our knowledge of the action of secondary generators, now called *transformers*. And so one of the chief lions this year at the Frankfort Exhibition was Prof. Ferraris. W. E. A.

(*To be continued.*)

THE GIRAFFE AND ITS ALLIES.

Although coming within that well-defined group of ruminants known as the Pecora, the Giraffe (the sole existing representative of the genus *Giraffa*) stands markedly alone among the mammals of the present epoch; although, on the whole, its nearest living relations appear to be the deer (*Cervidæ*). Moreover, not only is the giraffe now isolated from all other ruminants in respect of its structure, but it is also exclusively confined to that part of the African continent which constitutes the Ethiopian region of distributionists. When, however, we turn to the records of past epochs of the earth's history, we find that both the structural and distributional isolation of the giraffe are but features of the present condition of things. Thus, in regard to its distribution, we find that in the Pliocene epoch giraffes were abundant in Greece, Persia, India, and China; and we may therefore fairly assume that they were once spread over the greater part of the Palæarctic and Oriental regions. Then, again, with regard to their allies, the researches of palæontologists have been gradually bringing to light remains of several large extinct ruminants from various regions, which are more or less nearly related to the giraffe, but whose affinities appear to be so complex and so difficult to decipher, that not only do they remove the stigma of isolation from that animal, but even render it well-nigh impossible to give a definition of the group of more or less giraffe-like animals, by which it may be distinguished on the one hand from the deer (*Cervidæ*), and on the other from the antelopes (*Bovidæ*). Since an interesting account of a new extinct Giraffoid from the Pliocene deposits of Maragha in Persia has been recently given by Messrs. Rodler and Weithofer in the *Denkschriften* of the Vienna Academy, the present time is a suitable one to offer a brief *résumé* of the present state of our knowledge of this group of animals, and the different views which have been entertained as to the affinities of some of its members.

Among the chief structural peculiarities of the giraffe, the most noticeable is its great height, which is mainly produced by the excessive length of the neck and limbs. The fore-limbs are, moreover, longer than the hind ones, as is well shown by the circumstance that the radius, or main bone of the fore-leg, is longer than the tibia in the hind-leg; whereas, in other living ruminants the reverse condition obtains. The skull is more like that of the deer than of any other existing ruminants, this being shown by its general contour, and also by the presence of the large unossified space below the eye, which completely separates the lachrymal from the nasal bone; a condition but very rarely met with in the *Bovidæ*, although found in the skull of the water-buck. Then, again, the skull resembles that of the deer in the great elongation of the portion situated behind the eyes, *i.e.* the parietal region. The bony processes arising from the skull between the occiput and the eyes, and clothed in the living animal with skin, are not strictly comparable either with the antlers of the deer or the horn cores of the antelopes; in the young condition they are separate from the bones of the skull, with which, however, they unite as age advances. The whole of the frontal and nasal region is much swollen and inflated by the development of air-cells between the inner and outer layers of bone; and at the junction of the frontal and nasal bones there is a large oval hillock-like protuberance in the middle line, which is sometimes termed a third horn. This excessive inflation of the region of the face makes the appearance of this part of the skull very different from that of the deer, in which it is much flattened. The grinding or molar teeth of the giraffe are remarkable for the peculiar roughness of their external coating of enamel, and also for their broad and low crowns, which in the upper jaw lack the internal additional column occuring in those of most deer and many antelopes. These teeth are, however, more like those of the deer than those of other ruminants, although they can be distinguished at a glance from all others except the larger ones of the under-mentioned fossil forms.

Since a good deal depends on the similarity between the structure of the molar teeth of the giraffe and those of the extinct ruminants in question, it may be well to observe that the characters of the molar teeth among all the ruminants are of great importance in classification. Thus, these teeth in all the deer, although varying to a certain extent in the relative height of their crowns, present the same general structure, those of the upper jaw being comparatively short and broad, with a large internal additional column. Then, again, in the *Bovidæ* we may notice that each of the several groups into which the antelopes are divided, as well as the goats and sheep and the oxen, are severally distinguished by the characters of their molar teeth, and that, although the teeth of one group may approximate more or less closely to that of another, we do not find any instances where one member of a group possesses teeth of a totally different type from those of the other representatives of the same group. These facts strongly indicate that, when we meet with fossil ruminants having molar teeth of the very peculiar type met with in the giraffe, we shall be justified in considering that there must be a certain amount of relationship between the owners of such teeth.

Another marked peculiarity of the giraffe is that the humerus has a double groove for the biceps muscle, instead of the single one found in ordinary ruminants. In regard to its soft parts, the giraffe resembles the deer in the usual absence of the gall-bladder, although its reproductive organs are constructed more on the Bovine type.

With these preliminary remarks on some of the structural peculiarities of the giraffe, we may proceed to the consideration of its fossil allies. The genus which probably comes nearest to the giraffe is the imperfectly known *Vishnutherium*, founded upon part of a lower jaw from the Pliocene of Burma, but to which have been referred some upper molars and bones from the corresponding beds of the Punjab. This animal must have been considerably larger than the giraffe, and the upper molars are remarkable for the great flatness of the outer surfaces of their external columns, in which respect they come nearer to the corresponding teeth of the elk than do those of any other members of the group. The posterior cannon-bone, or metatarsus, assigned to this genus, although relatively much shorter than that of the giraffe, is more elongated and giraffe-like than the corresponding bone of any other fossil genus in which this part of the skeleton has been described. The cervical vertebræ are also more elongated and giraffe-like than those of any of the under-mentioned genera. It will of course be immaterial if these bones prove to belong to a genus distinct from *Vishnutherium*; their interest lying in the circumstance that they indicate the existence of an animal to a great extent intermediate between the giraffe and the following genus.

The genus *Helladotherium* was established upon the remains of a large giraffe-like ruminant from the Pikermi beds of Greece, to which a skull from the Indian Siwaliks, which had been previously regarded as referable to the female of *Sivatherium*, proved to belong. The Helladothere, of which the entire skeleton is known, was a hornless animal, of larger size than the giraffe, but with much shorter and stouter neck and limbs. The skull approximates in many respects to that of the giraffe, having the same long parietal region, but with a minor development of cells in the frontals, and the important difference that there is no unossified space below the eye. The limbs agree with those of the giraffe in the great relative length of the anterior pair, as is shown by the radius being considerably longer than the tibia. That the Helladothere was not the female of the Sivathere seems to be evident from the absence in the Pikermi beds of the antler-like cranial appendages of the latter, which are comparatively common in the Indian Siwaliks. The intimate affinity existing between the Helladothere and the giraffe has been admitted by all who have written on the subject.

The animal recently described by Messrs. Rodler and Weithofer from the Persian Pliocene, for which the hybrid name *Alcicephalus* has been proposed, tends to connect the Helladothere with the deer, and more especially the elk. Thus, in the first place, the front and hind limbs are approximately equal, the length of the radius and ulna being nearly the same. Then, again, from the total absence of air-cells in the frontal region of the skull, the middle of the face is nearly flat, and the orbits have their frontal borders in the plane of the face, instead of considerably below it, as in the Helladothere, and still more so in the giraffe. There is, however, no unossified space in front of the eye; although the whole contour of the skull is strikingly elk-like.

The conclusion to be drawn from these hornless forms appears to be that they serve to connect the giraffe with less aberrant ruminants, and more especially the *Cervidæ*, and also that the unossified vacuity in the skull of the giraffe is probably an acquired feature, since it is absent both in the extinct giraffoid genera, and in the earliest deer, like the Miocene *Amphitragulus*. Both giraffes and deer may, therefore, probably have had a common ancestor more or less closely allied to the lower Miocene genus *Gelocus*.

Leaving now these hornless forms, as to the affinities of which there has been no dispute, we have to turn our attention to another group provided with cranial appendages of very curious and still imperfectly understood structure, in regard to whose relationship exceedingly different views have been entertained. This group, so far as we know at present, seems to be confined to the Pliocene of India and Persia, being represented in the former area by the gigantic *Sivatherium*, *Bramatherium*, and *Hydaspitherium*, and in the latter by the much smaller *Urmiatherium*. In all these animals the skull is characterized by the extreme shortness of the parietal region, and the position of the horns or antlers immediately over the occiput; the elevated facial profile thus produced being in very striking contrast to the straight one of the deer. In *Bramatherium* and *Hydaspitherium* the cranial appendages rise from a massive common base, and the latter genus is distinguished from all the others by the presence of an unossified space below the eye, corresponding to that of the giraffe. Their molar teeth are very similar to those of the Helladothere. In the Sivathere, on the other hand, there is one pair of large branching and palmated cranial appendages rising from separate bases immediately above the occiput; and in addition to these a pair of much smaller conical ones placed immediately over the orbits. In general appearance the large palmated appendages are more like the antlers of the elk than those of any other existing ruminants; but the absence of a "burr" at their base indicates that they were not deciduous, while the deep arterial grooves on their surface suggest that they were clothed either with skin or with a horny substance. The molar teeth conform to those of the giraffe—and to a less degree the deer—having the same rugose enamel; but the ridges on the outer surfaces of those of the upper jaw are more developed than in the other extinct genera. A peculiarly giraffe-like and cervine feature in these upper teeth is the extension of the anterior extremity of the anterior crescent far towards the outer side of the crown. Lastly, the humerus of the Sivathere resembles that of the giraffe in the presence of a double groove for the biceps muscle; while the form of the terminal bones of the feet is almost identical in the two animals. In the small Persian *Urmiatherium*, which is known only by the hinder portion of the skull, it appears that the cranial appendages consisted of a pair of unbranched, somewhat compressed, and upright processes rising immediately above the occiput.

With regard to the affinities of this group, it has been argued that the shortness of the parietal region of the skull, and the position of the cranial appendages immediately above the occiput, indicate affinity with certain African antelopes, such as the Sassabi and its kindred (*Alcelaphus*). In that group of antelopes it is, however, perfectly clear that the features in question are acquired ones; the allied Blessbok scarcely possessing them in any degree. Again, the straightness of the cranial axis in the skull of Waller's gazelle (*Gazella walleri*) shows that the arching of this axis, which is so characteristic of most antelopes, is likewise a feature specially acquired among that group of animals. Moreover, apart from this evidence, no one who thinks for a moment on the subject can believe that the Sassabi, with its narrow sheep-like molars and true horns, and the Sivathere, with its broad giraffe-like molars and cranial appendages, which are neither true horns nor true antlers, can be anything approaching to first cousins; and yet if they are not so, it is perfectly evident that the similarity in the structure of their skulls must have been independently acquired. It is therefore abundantly clear that no arguments based on these resemblances will hold water; the true explanation probably being that the superficial similarity of their skulls is solely connected with the support of cranial appendages having a similar position in both groups.

It follows from this that, if a type of skull with a short parietal region, a curved basal axis, and horns placed immediately over the occiput, has been independently developed among the antelopes from a type of skull with a long parietal region, a straight basal axis, and horns placed over the orbits, there is no conceivable reason why a similar line of development should not have taken place among giraffe-like animals. Taking, therefore, into consideration that the Sivathere and its allies have molar teeth like those of the giraffe, that their cranial appendages could be derived from those of the latter by special modification and development better than from those of any other group, that their humerus has a double bicipital groove, that the terminal phalangeals of their feet are giraffe-like, and that the proportions of their limbs are only a step beyond those obtaining in the admittedly giraffoid Helladothere, the evidence in favour of regarding these animals as greatly modified Giraffoids is so strong as to be almost a certainty. Indeed, it appears most probable that we ought to regard the Sivathere and its allies as holding a somewhat analogous position among the Giraffoids to that occupied among the antelopes by the Sassabi and its cousins.

The writer has purposely refrained from making any reference to the large unossified suborbital vacuity in the skull of the Hydaspithere, as reasons have already been given for regarding that feature as an acquired one. If, however, that view be incorrect, the presence of this vacuity at once stultifies the statement that the Sivathere can have no kinship with the giraffe and the deer, on account of the absence of a similar vacuity; and its presence, so far as it goes, is also another argument against the Sassabi theory.

The last representative of the Giraffoid animals that we have to mention is the recently discovered *Samotherium*, from the Pliocene of Samos, a figure of the skull of which appeared in NATURE, illustrating an article on the extinct mammals of those deposits. In this animal, the elongated form and straight profile characteristic of the skull of the Giraffe are retained; and the teeth are almost indistinguishable from those of the latter. There is, however, no development of air-cells in the bones of the frontal region, so that the upper border of the orbit is approximated to the plane of the face; and the cranial appendages take the form of upright compressed processes rising immediately over the orbits. These appendages, which appear to have been inseparable from the bones of the forehead, are, indeed, very similar, both in form and position, to the horn-cores of certain extinct antelopes, but we are, of course, unacquainted with the nature of their covering. If, however, as seems to be undoubtedly the case, the Samothere is a Giraffoid, it would seem that we must here again regard this superficial resemblance to the antelopes as one independently acquired.

Finally, if the views expressed above are anywhere near the truth, it would appear that, in the Pliocene epoch, Giraffoid animals played a very important *rôle* among the ruminants, and that they have undergone modifications and developments fully as marked as those which we observe among the antelopes at the present day. Whether the circumstance that none of them, except the giraffe (which is obviously an animal incapable of further modification), appears to have obtained an entrance into Africa has been the chief reason why only a single representative of the group has survived to our own times may be a fair subject of conjecture, since after the Pliocene epoch both India and Europe seem to have been unsuited to the maintenance of many forms of large Artiodactyle Ungulates, as is proved by the disappearance from those regions of the hippopotamus, the giraffe, and a number of antelopes of African type. R. L.

PHOTOGRAPHIC MAGNITUDES OF STARS.

THE character of the image of a star photographed on a sensitized film; the relation between the intensity of the light photographed and the blackened disk produced; the influence of the time of exposure on the image—are questions now receiving much attention. For this reason, Dr. Scheiner's contribution to the subject, embracing, as it does, the latest results of the Potsdam Observatory, is especially welcome; but these results will not be accepted without great reserve, contravening, as they do, a theory, or at least an assertion, that has been very generally accepted, viz. that increasing the intensity of light is exactly equivalent to increasing the time of photographic exposure. A consequence of such a law would be that an additional magnitude would be impressed on the film by increasing the time of exposure two and a half times the length.

Such a law cannot be rigorously exact, and its stoutest supporters have been careful to confine its application "within limits." But Dr. Scheiner's contention is that, owing to the complex character of the disk produced on the film, such a principle is a very unsafe guide, either as a rule for the determination of the feeblest magnitude impressed on the negative, or as offering a satisfactory explanation of the growth of the diameter or area.

In the first place, there is evidence of want of uniformity of actinic action throughout the whole extent of the stellar disk. A mean intensity (i) may be assumed at a certain distance (r) from the centre of the image, where the intensity is I. This centre will not be a geometrical point, but, owing to atmospheric and other disturbances, will occupy a small area of radius (ρ). The intensity (i) at distance (r) will depend materially on the increase of the area (ρ), which may be represented by $\psi(\rho)$. Consequently, the simplest expression for $i = \mathrm{I}\psi(\rho)e^{ar}$, where a is the coefficient of absorption of the sensitive film. On comparing two stellar disks, formed on the same emulsion, and treated by the same developer, this expression becomes

$$\frac{t_0}{t_1} = \frac{\mathrm{I}_1\,\psi(\rho_1)}{\mathrm{I}_0\,\psi(\rho_0)}e^{a(r_1-r_0)},$$

and, if the disks be on the same plate, $\rho_1 = \rho_0$ and $t_1 = t_0$, so that the formula can be simplified to

$$a(r_0-r_1) = \log\frac{\mathrm{I}_1}{\mathrm{I}_0}. = \frac{0{\cdot}4}{\text{mod.}}(m_1 - m_0)$$

In order to derive the relation between diameters and exposure, put $\mathrm{I}_0 = \mathrm{I}_1$, and then

$$\log\frac{t_0}{t_1} = a(r_1 - r_0).$$

It is not likely that such an expression has any other value than to serve as a convenient formula for interpolation. The variable character of a under different conditions, but always depending on the time of exposure, is shown by the following table:—

Exposure. m. s.	Instrument.	a.	Instrument.	a.
1 0	Reflector	4·99	5-in. refractor	4·12
2 0	,,	4·57	,,	5·09
4 0	,,	4·67	,,	5·47
8 0	,,	4·89	,,	5·89
16 0	,,	5·39	,,	7·51
0 24	13-in. refractor	3·18	13-in. refractor	2·67
1 0	,,	3·16	,,	2·20
2 30	,,	3·33	,,	2·48
6 15	,,	3·33	,,	3·00
15 38	,,	4·48	,,	—

Another well-known formula in which magnitude is made to depend on diameter is $m = a - b \log \mathrm{D}$, and in this case b is shown, notwithstanding Dr. Charlier's results to the contrary, to be a function of the time of exposure. The results are as follows:—

Time of exposure. h. m.	b Charlier.	Time of exposure. m. s.	b Scheiner.
0 13	6·719	0 24	5·17
1 30	6·779	1 0	6·35
2 0	6·683	2 30	7·06
3 0	6·814	6 15	8·08

The disagreement is conspicuous, but the explanation offered by Dr. Scheiner is scarcely satisfactory. He would ascribe the constancy in the value of b, found by Dr. Charlier, to the fact that in his experiments there is always a large absolute value of the time coefficient. It will, however, be observed that the ratio between Dr. Charlier's extreme exposures is not greatly different from that which obtains in Dr. Scheiner's experiments.

If it be admitted that the product of intensity by the time is *not* a constant quantity, it becomes a matter of great practical importance to determine what is gained on a photographic plate by prolonged exposure. This question forms the real investigation of Dr. Scheiner's two papers, and though some of his results may be questioned, yet the general issue is so grave and disquieting that it may not be utterly ignored. Passing over the details of his method of examination, and the precautions taken to insure accurate results, for which the reputation of the Potsdam Observatory is a sufficient guarantee, Dr. Scheiner presents the following table, in which is exhibited the faintest magnitude which, under certain varied circumstances, can be detected on a photographic plate:—

Time of exposure.		Faintest magnitude.			
m.	s.	Plate I.	Plate II.	Plate III.	Plate IV.
0	24	9·0	6·4	7·7	8·2
1	0	9·4	7·25	8·3	8·75
2	30	9·9	7·7	8·55	9·3
6	15	10·6	8·45	9·3	9·65
15	38	—	8·85	9·7	—

It will be noticed that while each successive exposure is 2·5 that of the preceding, the corresponding gain in light is considerably less than one magnitude. From each of the four plates the gain is as follows:—

	Gain in mag.
Plate I.	0·53
,, II.	0·61
,, III.	0·50
,, IV.	0·48

The mean is 0·53—that is to say, instead of one magnitude being gained by continued exposure through each successive interval, the actual gain is only half a magnitude. The exception that might be taken to these experiments is, that the detection of the feeblest stars on a plate is a matter of doubt and great practical difficulty. Dr. Scheiner has, however, availed himself of a second test by counting the stars on a plate after various exposures. With this view two plates were taken of the region round ϵ Orionis, one with an exposure of one hour, the other with eight hours' exposure. Therefore, if 2·5 times the exposure produced stars a magnitude fainter, there ought to be a gain of more than two magnitudes on the second plate, and it may be assumed that the number of stars impressed would follow the known law. On the one-hour plate were found 1174 stars, on the eight-hour 5689. There ought to have been on the long-exposed plate over 10,000 stars, so that roughly speaking only one-half of the stars given by the law were photographed. Further, Argelander has catalogued within this area 125 stars, and therefore it might have been anticipated from the law of increase that some 10,000 stars would have been visible on the one-hour plate.

This margin is too great to be readily explained away. Of course, there is the same difficulty in perceiving the minute dots that represent the faintest stars as in the former case, and further, it is possible that the law of average increase of the number of stars did not hold in this particular part of the sky. It is not to be expected that a law, which applies with more or less accuracy *on the average* to the whole of the sky, is necessarily fulfilled on any small portion, such as the ten-thousandth part. If the stars are not in the heavens, they cannot be photographed. Evidently, it would be unlikely that on every thousandth part of *that* plate would be found the thousandth part of the total number of stars impressed.

But allowing for errors of exaggeration and observation, the result is very interesting, and not a little alarming as implying that photography is not so powerful an engine as was at first anticipated, and that, to accomplish the full hope of all that was expected of it, longer exposure and consequently a greater expenditure of time will be needed. Dr. Scheiner gives a little table, which shows that if a star of the 9·5 mag. be registered in 24 seconds, then in 190 minutes a star of the 16·5 mag. will be photographed, supposing a whole magnitude to be gained by successively multiplying the exposure by 2·5. But if the gain be only 0·5 in this interval, then the faintest star impressed will be only 13·0 mag., even after this long exposure. If 0·6 of a mag. be the rate of increase, then the 13·6 mag. will be seen; if 0·7, then 14·4 mag. The truth will probably be found near this latter limit.

NOTES.

THE second International Folk Lore Congress meets at the rooms of the Society of Antiquaries this afternoon, when an address will be delivered by Mr. Andrew Lang, the President. Three subjects are to be considered—folk tales, mythology, and institutions and customs. To each of these subjects a day will be devoted. The proceedings will be brought to an end on Wednesday morning next.

THE Iron and Steel Institute will meet at the Woolwich Arsenal on Tuesday next. The members are to be conducted over the manufacturing departments at the Arsenal, and will see quick-firing and machine guns in practice. On the following day the Institute will conclude its meeting at the Institution of Civil Engineers.

THE third biennial session of the International Statistical Congress was opened at Vienna, on Monday, by Baron Gautsch, the Austrian Minister of Public Instruction. An address was delivered by Sir Rawson Rawson, the President.

THE seventeenth Annual Congress of the Sanitary Association of Scotland was held in Edinburgh last week. Dr. Farquharson, M.P., President of the Congress, delivered an address "On a Model Hygienic State, or a Glance at the Sanitation of the Future." In the course of his remarks he urged the necessity for more organized attention being given in Parliament to hygienic matters, and advocated the appointment of a Minister of Public Health.

THE Harveian Oration will be delivered at the Royal College of Physicians, by Dr. W. H. Dickinson, at the Royal College of Physicians, on Monday, October 19, at 4 o'clock.

WE referred last week to the death of Prof. W. Ferrel. He was born on January 29, 1817, and since the foundation of the *American Meteorological Journal* he was a frequent contributor to that paper, from which we take most of the following details of his life. During his boyhood he was kept rather closely at work on his father's farm, and with the first money he earned, he bought a copy of Park's "Arithmetic." Having also a liking for astronomical studies, he used to draw a number of diagrams upon the doors of his father's farm, describing circles with the prongs of a pitchfork. In 1839, he entered one of the Colleges in Pennsylvania, and graduated at Bethany College in 1844. In 1857, he became an assistant in the office of the "American Ephemeris and Nautical Almanac," and subsequently entered the U.S. Coast Survey and the Signal Office, from which last he retired in 1886. He was elected a member of the National Academy of Sciences in 1868. Ferrel is described as an extremely diffident man, and he never once sought position; every official position that he occupied having been offered to him. His first paper bearing directly on meteorology was published in 1856, with reference to the deflective effects of the earth's rotation upon the motions of the atmosphere; and this paper, which has done much towards establishing meteorology on a scientific basis, was subsequently revised and reprinted as one of the professional papers of the Signal Service, under the title "Motions of Fluids and Solids on the Earth's Surface." In this treatise he proposed a complete analytical investigation of the general motions of the fluids surrounding the earth. These papers received considerable attention and discussion soon after publication, especially in France; in America and England they were overlooked until recent years, but they are now recognized as fundamental propositions in the study of meteorology. He also wrote various articles on the tides, which are of equal significance with those on the motions of the atmosphere, and he constructed a "maxima and minima tide-predicting machine," which is now in use at the Coast Survey Office in Washington. The last of his numerous works upon meteorology was a "Popular Treatise on the Winds," published in 1889, and reviewed at length in our columns (vol. xli. p. 124). In this work he has explained at length, and with great clearness, many points which in his other writings have been too mathematical to allow of their being generally understood.

We have already recorded with regret that Miss E. A. Ormerod has considered it desirable to resign her post of Consulting Entomologist of the Royal Agricultural Society, which she has occupied for about nine years, having been appointed in 1882. We understand that her reasons for resignation are partly on account of health, as in wet and cold weather she cannot take the requisite journeys to attend Committees without risk; partly on account of claims made of power of Council to direct her to render service in reporting elsewhere, and claims also made as to use of information in her possession beyond what the terms of her engagement granted. These claims, we understand, have been withdrawn, but Miss Ormerod considers she can work more efficiently when freed from the anxieties and possible ties which public office necessarily brings with it. Miss Ormerod's agricultural entomological work, as shown by her annual reports, has now been going on steadily for at least fourteen years, having been begun several years before she was elected to the staff of the Royal Agricultural Society; and this she purposes to continue precisely as before in all respects, whether as regards replies to inquiries, or publication by herself of observations in the form of yearly reports.

In an article on Hooker's "Icones Plantarum," in our last issue (p. 498) we attributed the plates of the earlier volumes to Sir William Hooker. Sir Joseph Hooker informs us that they are all the work of Mr. W. H. Fitch.

A valuable report, by Mr. A. E. Shipley, on an orange disease in Cyprus, caused by a scale insect, is published in the September number of the *Kew Bulletin*. The disease appears to have been noticed in Cyprus for the last six or eight years. The particular insect to which it is due is *Aspidiotus aurantii*, Maskell, a member of the sub-family *Diaspinæ*, which, with some others, compose the family *Coccidæ*. Mr. Shipley gives an account of the life-history of this insect, and then describes the various methods of dealing with it. The most successful of these methods is the gas treatment, a full description of which, by Mr. Coquillett, is quoted by Mr. Shipley from Bulletin No. 23 of the U.S. Department of Agriculture, Division of Entomology. We may note that Mr. Shipley is anxious to obtain examples of *Coccidæ* which infest plants, and examples of nematode worms parasitic in plants, with the affected parts of their respective hosts.

The *Kew Bulletin* for September, besides Mr. Shipley's report on orange scale in Cyprus, contains sections on the rediscovery of gutta-percha trees at Singapore, on a new process for recovering some portion of the gutta-percha which is left in the bark of the trees after collection by the ordinary native method, on the fodder plant Tagasaste, and on Kangra buckwheat.

The *Oesterreichische Botanische Zeitung* for September contains a report of Dr. A. v. Degen's botanical excursion to the island of Samothrace, and of Dr. R. F. Solla's to Southern Istria.

The fourth number of the first volume of *Contributions from the U.S. National Herbarium*, published under the auspices of the Department of Agriculture at Washington, consists of a description, by Mr. J. N. Rose, of the plants collected by Dr. E. Palmer in 1890 in Western Mexico and Arizona. Forty-five new species are described, and several of these are illustrated by plates. Most of the new species obtained were from the neighbourhood of Alamos, a mining town of about 10,000 inhabitants, situated 180 miles south-east from Guaymas, at an altitude of about 1275 feet, where there are both a dry spring and a rainy autumn flora, very different from one another. Dr. Palmer has again started for a year's exploration of Western Mexico.

Some valuable and interesting notes on the fertilization of South African and Madagascar flowering plants, by Mr. G. F. Scott Elliot, appear in *Annals of Botany* (vol. v., No. xix., August 1891), and have also been issued separately. They represent much work done during a two years' botanical trip. While travelling, Mr. Elliot found it impossible to make as thorough and complete observations as are really required for a proper comprehension of all the adaptations of a flower to insect visitors; but he tried to collect every insect which he saw visiting flowers, and brought home with him a numbered collection. Most of the forms secured by him had not previously been studied in their native haunts.

The Transactions of the Liverpool Biological Society for 1891 contain an important paper by Mr. G. Murray on the Distribution of Marine Algæ in space and in time. The author compares the algal flora of three widely separated regions—the Arctic Sea, the West Indian region, and Australia; and shows in a table how many genera and species are common to any two of the regions. The number of known species of seaweeds is given as 259 in the Arctic Sea, 788 in the West Indies, and 1132 in Australia. Only twelve species are common to all three regions, and of these four belong to the Ulveæ.

A great Mining Exhibition is to be opened at Johannesburg next July, and exhibits from all parts of the world are invited.

The administration report of the Marine Survey of India for the official year 1890–91, by Captain R. F. Hoskyn, has been published. For some time notices had been received from several vessels, which seemed to indicate that the shoals lying off the eastern coast between Ennore and Pulicat were extending seaward. In the early part of 1890, therefore, the *Investigator* proceeded to this neighbourhood, and made a survey of the coast between these two places, carrying the soundings out to the 100-fathom line. The result showed that no material change had taken place in the size or position of the shoals from the time of the previous survey. The work of the season ended on May 7, when the *Investigator* arrived at Bombay. In October last a new season's operations began, and at the time when the report was written (March 9, 1891) the survey of the eastern coast of Hindustan had been completed to lat. 16° 50′ N.

The report of Dr. A. Alcock, surgeon-naturalist on board the *Investigator*, is one of great interest. It is given as an appendix to that of Captain Hoskyn. We have already referred to Dr. Alcock's account of the general results of his deep-sea work. It may be noted that on November 3, 1890, the deepest haul ever made in Indian seas—1,997 fathoms—was successfully carried out in lat. 9° 34′ N., long. 85° 43′ 15″ E., the bottom being Globigerina ooze with pieces of water-worn pumice, and the bottom-temperature being 35° F. About 2200 fathoms of wire were veered. The following was the entire take:—There were three species of siliceous sponges and numerous detached spicules of *Hyalonema*; a large sea-anemone of a salmon-pink colour, with bright red tentacles; a mutilated specimen of the Brisingoid *Freyella benthophila*, Sladen, a fine new species of *Hyphalaster*, and a small, probably new, species of *Marsipaster* with the nidamental pouches widely open and full of ova; two species of Ophiurids, one of which is *Ophiomastus*; three species of Holothurians including *Echinosoma*; numerous specimens of a long-stalked Ascidian; two specimens of a very large species of *Amphipod*, a blind Crangonid, three species of macrurous Crustaceans, and a small *Scapellum*; a small Lamellibranch; and a number of empty annelid tubes, some of which were constructed of Foraminifera shells, while others consisted of agglutinated silky (siliceous) threads.

Mr. W. L. Dallas, assistant meteorological reporter to the Government of India, has written a valuable paper on the meteorology and climatology of Northern Afghanistan, the facts having been collected by officers connected with the Afghan Delimitation Commission. Taking the whole of the record into consideration, Mr. Dallas thinks it may safely be maintained that in the great majority of cases the disturbed weather which appears over North-Western India during the winter and spring months is the result of disturbances, which either effect simultaneously the whole region comprising Afghanistan, Baluchistan, and North-Western India, or which have appeared first over Afghanistan and secondly over India, and that these disturbances have seldom originated in India itself or are confined to India.

We have received from the Meteorological Council their Quarterly Weather Report for July to December 1880, and Monthly Weather Report for May to December 1887. The Quarterly Reports, which commenced with the year 1869, contain, in addition to the monthly and five-daily means of the observations made at the seven observatories, plates of the continuous curves of the self-recording instruments, which have been etched at the Office, and are perhaps the most complete and perfect series of meteorological curves hitherto published, and also a condensed account of the most important meteorological changes of the period. The Quarterly Reports are now discontinued, and the publication of a Monthly Weather Report was undertaken in 1884 in substitution for the Quarterly Report, while the hourly observations and means have been published in a separate volume. This Report contains the results of observations made at a considerable number of stations, together with a chronicle of the weather, and charts showing the average conditions of the various elements. Both the Quarterly and Monthly Weather Reports also contain a number of elaborate discussions of various allied subjects. The Monthly Reports in the form hitherto issued have been modified; and instead of appearing as a separate work, a Monthly Summary of the Weather, on a more concise plan, has been added to the Weekly Weather Report, commencing with the year 1888. With the exception of the years 1881–83 we have therefore a continuous and valuable record of the weather—in addition to such as is afforded by the Daily and Weekly Reports—since 1869, and we believe it is the intention of the Council to connect the gap between the Quarterly and Monthly Reports at an early date, by a discussion of the weather for that period. We shall refer in a future number to the publications which deal with the observations and results at the Stations of the Second Order, which are more particularly of a climatological character, without discussions of current weather.

The Park Commissioners of Boston, U.S., have set apart three parcels of land for the establishment, by the Boston Society of Natural History, of zoological gardens and aquaria. It is essential that 200,000 dollars should be raised before any attempt can be made to realize the scheme as a whole, but if a third of the amount were subscribed, one of the two proposed aquaria might at once be instituted. An appeal has been made by the Society to the people of Boston for the necessary funds, and it will be strange if it does not meet with a ready and liberal response. The Society is sanguine enough to think that every public-spirited citizen will see in the scheme "an addition to the forces which increase the intelligence of the voter, and thereby tend to make Boston a more desirable place of residence."

Students of the Ice Age will read with interest a paper by Mr. N. S. Shaler on the antiquity of the last glacial period, submitted to the Boston Society of Natural History, and printed in the latest instalment of the Society's Proceedings. Mr. Shaler differs decidedly from those geologists who suppose that the end of the glacial period is probably not very remote from our own day. One of the strongest of his arguments is derived from the distribution of the vegetation which in America has regained possession, by migration, of the glaciated district. We must conceive, he points out, that as the ice retreated and gradually disappeared from the surface a considerable time elapsed before existing forests attained their organization. He assumes as certain that the black walnut and the pignut hickory, between Western Minnesota and the Atlantic coast, have advanced, on the average, a distance of 400 miles north of the ancient ice front to which their ancestors were driven by the presence of the glacial sheet. For several reasons he believes that the northward progress of these forms must have been due mainly, not to the action of streams or tornadoes, but to the natural spread of the seed from the extremities of boughs, and to the carriage of the seed by rodents. But allowing for every conceivable method of transportation, he argues that a period of ten or even twenty thousand years is wholly inadequate to account for the present distribution of these large-seeded trees. If they occurred only sporadically in the northernmost part of the field they occupy, their implantation might be regarded as due to chance action. The fact, however, that they extend from the Atlantic to Minnesota indicates that the advance was accomplished by causes of a general and continuous nature.

"Water-birds that live in the Woods" formed the subject of an interesting paper read lately by Mr. G. B. Sennett before the Linnæan Society of New York. About a dozen species were dealt with, the most interesting of them perhaps being the tree ducks (*Dendrocygna autumnalis et fulva*). The former is found in the heaviest timber along the Rio Grande of Texas, at Lomita, and as this river furnishes no sort of food, it adapts itself to circumstances and feeds upon seeds or grain. These ducks will alight upon a stalk of growing corn with the ease of a blackbird, and are quite at home among the lofty trees where they make their nests. They do not resort to the river, which is so cold and muddy, from the melting snows of the mountains whence it flows, that all vegetable and animal life save the gar-pike is wanting. No ducks of any kind are found upon it. A flock of cormorants, about four miles long and one mile and a half wide, was once seen by Mr. Sennett in Minnesota.

Sparrows do not seem to lose in New Zealand any of the audacity for which they are famous in Europe. In a paper read some time ago before the New Zealand Institute, and now printed in the Transactions, Mr. T. W. Kirk gives an example of what he calls their "daring and cool impudence." Between Featherston and Martinborough he heard one day a most unusual noise, as though all the small birds in the country had joined in one grand quarrel. Looking up, he saw a large hawk (*C. gouldi*—a carrion-feeder) being buffeted by a flock of sparrows. They kept dashing at him in scores, and from all points at once. The unfortunate hawk was quite powerless; indeed, he seemed to have no heart left, for he did not attempt to retaliate, and his defence was of the feeblest. At last, approaching some scrub, he made a rush indicative of a forlorn hope, gained the shelter, and there remained. Mr. Kirk watched for fully half an hour, but he did not reappear. The sparrows congregated in groups about the bushes, keeping up a constant chattering and noise, evidently on the look-out for the enemy, and congratulating themselves upon having secured a victory.

If we may judge from the Report of the Department of Agriculture, Victoria, for the year 1889–90, the farmers of that colony are likely to benefit largely by the work of the agricultural authorities. The Department is efficiently organized, and has a thoroughly scientific conception of the nature of its duties. Mr. D. McAlpine, who has been appointed consulting vegetable pathologist, presents the following summary of the tasks undertaken by his particular section: (1) special investigations concerning the rust of wheat, oats, barley, and other cereals, and, connected with that, the question of rust on various grasses—native and imported; (2) investigations of the life-histories of the various fungus pests, and a knowledge of the best time to cope with them; (3) reports upon diseased specimens sent in from different parts of the colony, and the best known remedies for the palliation or prevention of such diseases; (4) collection of specimens of the various diseases due to fungi, and the subsequent formation of a museum for educational purposes; (5) delivery of lectures in different centres on the fungus pests most prevalent there; (6) preparation of illustrated handbooks, describing the nature of the various diseases and the remedies to be employed where possible; (7) testing various fungicides and the best methods of applying them; (8) visiting different districts in order to find out prevailing and injurious fungi; (9) contributing periodic reports to the official Bulletin of the Department.

IN the Proceedings of the Bath Natural History and Antiquarian Field Club (vol. vii. No. 2), Mr. J. F. Mostyn Clarke gives an account of the geological formations exposed in the cuttings of the Bridgwater Railway, the construction of which opened up a continuous line of excavation through the heart of the Polden Hills. Mr. Clarke had charge of the construction of the railway until near the completion of the earthwork, so that he had excellent opportunities for making careful observations. Geologists may be glad to have his description of the strata when the slopes of the cuttings are overgrown.

MESSRS. LONGMANS, GREEN, AND CO. have published the sixth edition of "An Elementary Treatise on the Integral Calculus," by Dr. Benjamin Williamson, F.R.S. In this edition the work has been revised and enlarged.

MESSRS. MITSCHER AND RÖSTELL, 61*a* Jägerstrasse, Berlin, have issued an important list of books which they have for sale. The works relate to the various departments of botany.

TWO communications upon the volatile carbonyl compounds of platinum, from Dr. Pullinger, of Tübingen, and Drs. Mylius and Foerster, of Charlottenburg, appear in the last number of the *Berichte*. Since the preparation of the remarkable carbonyl compounds of nickel and iron by Messrs. Mond, Langer, and Quincke, these platinum compounds, discovered by Schutzenberger in the year 1868, have become more interesting, and the two papers now before us add considerably to our knowledge of them. They are compounds containing platinum, chlorine, and carbon monoxide, and Schutzenberger assigned to them the formulæ $PtCl_2CO$, $PtCl_2 . 2CO$, and $2PtCl_2 . 3CO$ respectively. He obtained them by heating spongy platinum to a temperature of 250° C. in a stream first of chlorine and afterwards of carbon monoxide. The volatile, readily fusible, and crystalline sublimate obtained contained a mixture of the three, and he effected a separation by extraction with carbon tetrachloride, in which the three compounds are differently soluble. They are well defined by their melting-points, which are 194°, 142°, and 130° C. respectively. They are decomposed by water with separation of platinum, formation of hydrochloric acid, and evolution of carbon dioxide, and also, in case of the second and third compounds, of carbon monoxide. The most stable of these compounds and the best investigated is the simpler one, $COPtCl_2$. It appears to possess a distinctly basic character, so that it is able to combine with hydrochloric acid to form a compound, $COPtCl_2 . HCl$; this compound is formed in solution when the crystals are dissolved in concentrated hydrochloric acid. The two other compounds are decomposed by hydrochloric acid, losing carbon monoxide and forming the hydrochloride of the first compound. On evaporation of the hydrochloric solution, the first compound is left in needle-shaped crystals. When phosgene gas, $COCl_2$, is passed over the crystals, drops of liquid are formed, which consist of a solution of the compound in liquefied carbonyl chloride. In addition to these compounds, the bromide and iodide corresponding to the compound $COPtCl_2$ have been prepared. When the hydrochloric acid solution of the latter is evaporated on a water-bath in a stream of hydrobromic acid gas, and the resulting compound extracted with benzene, the filtered solution deposits, on cooling, orange-red needles of the bromide, $COPtBr_2$. The bromide has likewise been obtained by Dr. Pullinger, by passing carbon monoxide over heated platinous bromide. Similarly, the iodide has been prepared by evaporating crystals of the chloride with excess of hydriodic acid solution, and treating the residue with warm benzene. The crystals of the iodide, $COPtI_2$, which separate from the benzene solution on cooling, are deep red in colour, with a violet surface reflection. The chloride, bromide, and iodide exhibit a beautifully graduated difference of properties. Thus the chloride is yellow, the bromide orange, and the iodide red in colour. The melting-points are 194°, 181°, and 140° respectively. The chloride is readily, the bromide difficultly, and the iodide not at all volatile. The chloride is strongly hygroscopic, the bromide less so, and the iodide permanent. In addition to these compounds, another has been obtained by Dr. Pullinger, of the composition $PtCl_2 . 2COCl_2$, in the form of non-volatile yellow crystals, readily soluble in water, from which it recrystallizes unchanged. It appears to be the most stable of all these platinum compounds, but is only obtained in very small quantity.

OUR ASTRONOMICAL COLUMN.

INFLUENCE OF ABERRATION UPON OBSERVATIONS OF SOLAR PROMINENCES.—Some recent observations of the development and movement of solar prominences have led M. Fizeau to consider the influence that the aberration of light may exercise upon them. A note relative to such an inquiry is contained in *Comptes rendus* for September 7. It is well known that, in consequence of aberration, the longitude of the sun, and therefore of the prominences, is diminished by the amount of the constant, $20''\cdot445$—an apparent displacement depending upon the earth's orbital velocity. And it results from this that if a prominence is developed in the neighbourhood of the ecliptic, and the luminous matter of which it is composed has a velocity of translation equal to the velocity of the earth in its orbit, its position will suffer a displacement of $20''\cdot445$, which may be added to the effect due to the earth's motion, or otherwise, according to the direction of propagation, and thus give rise to corresponding variations in distances from the edge of the sun. As a matter of fact, however, the velocities of prominences are not uniform, and do not commonly attain the required value; nevertheless it seems that the high velocities which have been determined must give rise to apparent movements which depend upon the laws of aberration, and which ought to be taken into account in precise measurements.

Another point touched upon in the communication to which reference has been made is the physical nature of prominences. The simplest hypothesis is that they represent clouds of incandescent hydrogen and other metallic vapours; but M. Fizeau favours the idea that their visibility is the result of the passage of electrical discharges through gaseous material.

NEW ASTEROIDS.—The 317th asteroid was discovered by Charlois on September 8, and the 318th on September 11.

SOME OF THE POSSIBILITIES OF ECONOMIC BOTANY.[1]

OUR Association demands of its President, on his retirement from office, some account of matters connected with the department of science in which he is engaged.

The subject which I have selected for the valedictory address deals with certain industrial, commercial, and economic questions: nevertheless it lies wholly within the domain of botany. I invite you to examine with me some of the possibilities of economic botany.

---

[1] Abstract of the Presidential address delivered before the American Association for the Advancement of Science, at Washington, August 1891, by George Lincoln Goodale, M.D., LL.D., Fisher Professor of Natural History, Harvard University, Cambridge, Mass., U.S.A.

Of course, when treating a topic which is so largely speculative as this, it is difficult and unwise to draw a hard and fast line between possibilities and probabilities. Nowadays possibilities are so often realized rapidly that they become accomplished facts before we are aware.

In asking what are the possibilities that other plants than those we now use may be utilized we enter upon a many-sided inquiry. Speculation is rife as to the coming man. May we not ask what plants the coming man will use?

There is an enormous disproportion between the total number of species of plants known to botanical science and the number of those which are employed by man.

The species of flowering plants already described and named are about one hundred and seven thousand. Acquisitions from unexplored or imperfectly explored regions may increase the aggregate perhaps one-tenth, so that we are within very safe limits in taking the number of existing species to be somewhat above one hundred and ten thousand.

Now if we should make a comprehensive list of all the flowering plants which are cultivated on what we may call a fairly large scale at the present day, placing therein all food and forage plants, all those which are grown for timber and cabinet woods, for fibres and cordage, for tanning materials, dyes, resins, rubber, gums, oils, perfumes, and medicines, we could bring together barely three hundred species. If we should add to this short catalogue all the species, which, without cultivation, can be used by man, we should find it considerably lengthened. A great many products of the classes just referred to are derived in commerce from wild plants, but exactly how much their addition would extend the list, it is impossible in the present state of knowledge to determine. Every enumeration of this character is likely to contain errors from two sources: first, it would be sure to contain some species which have outlived their real usefulness; and, secondly, owing to the chaotic condition of the literature of the subject, omissions would occur.

But after all proper exclusions and additions have been made, the total number of species of flowering plants utilized to any considerable extent by man in his civilized state does not exceed, in fact it does not quite reach, one per cent.

The disproportion between the plants which are known and those which are used becomes much greater when we take into account the species of flowerless plants also. Of the five hundred ferns and their allies we employ for other than decorative purposes only five; the mosses and liverworts, roughly estimated at five hundred species, have only four which are directly used by man. There are comparatively few Algæ, Fungi, or Lichens which have extended use.

Therefore, when we take the flowering and flowerless together, the percentage of utilized plants falls far below the estimate made for the flowering alone.

Such a ratio between the number of species known and the number used justifies the inquiry which I have proposed for discussion at this time—namely, can the short list of useful plants be increased to advantage? If so, how?

This is a practical question; it is likewise a very old one. In one form or another, by one people or another, it has been asked from early times. In the dawn of civilization, mankind inherited from savage ancestors certain plants, which had been found amenable to simple cultivation, and the products of these plants supplemented the spoils of the chase and of the sea. The question which we ask now was asked then. Wild plants were examined for new uses; primitive agriculture and horticulture extended their bounds in answer to this inquiry. Age after age has added slowly and cautiously to the list of cultivable and utilizable plants, but the aggregate additions have been, as we have seen, comparatively slight.

The question has thus no charm of novelty, but it is as practical to-day as in early ages. In fact, at the present time, in view of all the appliances at the command of modern science and under the strong light cast by recent biological and technological research, the inquiry which we propose assumes great importance. One phase of it is being attentively and systematically regarded in the great experiment stations, another phase is being studied in the laboratories of chemistry and pharmacy, while still another presents itself in the museums of economic botany.

Our question may be put in other words, which are even more practical. What present likelihood is there that our tables may, one of these days, have other vegetables, fruits, and cereals, than those which we use now? What chance is there that new fibres may supplement or even replace those which we spin and weave, that woven fabrics may take on new vegetable colours, that flowers and leaves may yield new perfumes and flavours? What probability is there that new remedial agents may be found among plants neglected or now wholly unknown? The answer which I shall attempt is not in the nature of a prophecy; it can claim no rank higher than that of a reasonable conjecture.

At the outset it must be said that synthetic chemistry has made and is making some exceedingly short cuts across this field of research, giving us artificial dyes, odours, flavours, and medicinal substances, of such excellence that it sometimes seems as if before long the old-fashioned chemical processes in the plant itself would play only a subordinate part. But although there is no telling where the triumphs of chemical synthesis will end, it is not probable that it will ever interfere essentially with certain classes of economic plants. It is impossible to conceive of a synthetic fibre or a synthetic fruit. Chemistry gives us fruit-ethers and fruit-acids, and after a while may provide us with a true artificial sugar and amorphous starch; but artificial fruits worth the eating or artificial fibres worth the spinning are not coming in our day.

Despite the extraordinary achievements of synthetic chemistry, the world must be content to accept, for a long time to come, the results of the intelligent labour of the cultivator of the soil and the explorer of the forest. Improvement of the good plants we now utilize, and the discovery of new ones, must remain the care of large numbers of diligent students and assiduous workmen. So that, in fact, our question resolves itself into this: Can these practical investigators hope to make any substantial advance?

It seems clear that, except in modern times, useful plants have been selected almost wholly by chance, and it may well be said that a selection by accident is no selection at all. Nowadays, the new selections are based on analogy. One of the most striking illustrations of the modern method is afforded by the utilization of bamboo fibre for electric lamps.

Some of the classes of useful plants must be passed by without present discussion; others alluded to slightly, while still other groups fairly representative of selection and improvement will be more fully described. In this latter class would naturally come, of course, the food-plants known as

I. THE CEREALS.

Let us look first at these.

The species of grasses which yield these seed-like fruits, or as we might call them for our purpose seeds, are numerous; twenty of them are cultivated largely in the Old World, but only six of them are likely to be very familiar to you—namely, wheat, rice, barley, oats, rye, and maize. The last of these is of American origin, despite doubts which have been cast upon it. It was not known in the Old World until after the discovery of the New. It has probably been very long in cultivation. The others all belong to the Old World. Wheat and barley have been cultivated from the earliest times; according to De Candolle, the chief authority in these matters, about four thousand years. Later came rye and oats, both of which have been known in cultivation for at least two thousand years. Even the shorter of these periods gives time enough for wide variation, and as is to be expected there are numerous varieties of them all. For instance, Vilmorin, in 1880, figured sixty-six varieties of wheat with plainly distinguishable characters.

If the Chinese records are to be trusted, rice has been cultivated for a period much longer than that assigned by our history and traditions to the other cereals, and the varieties are correspondingly numerous. It is said that in Japan above three hundred varieties are grown on irrigated lands, and more than one hundred on uplands.

With the possible exception of rice, not one of the species of cereals is certainly known in the wild state.

It is out of our power to predict how much time would elapse before satisfactory substitutes for our cereals could be found. In the improvement of the grains of grasses other than those which have been very long under cultivation, experiments have been few, scattered, and indecisive. Therefore we are as badly off for time-ratios as are the geologists and archæologists in their statements of elapsed periods. It is impossible for us to ignore the fact that there appear to be occasions in the life of a species when it seems to be peculiarly susceptible to the influences of surroundings. A species, like a carefully laden ship, represents a balancing of forces within and without. Disturbance may come through variation from within, as from a shifting of the cargo, or in some cases from without. We may suppose both forces to be active in producing variation, a change in the internal condition rendering the plant more susceptible to any change in its surroundings. Under the influence of any marked disturbance, a state of unstable equilibrium may be brought about, at which times the species as such is easily acted upon by very slight agencies.

One of the most marked of these derangements is a consequent of cross-breeding within the extreme limits of varieties. The resultant forms in such cases can persist only by close breeding or by propagation from buds or the equivalents of buds. Disturbances like these arise unexpectedly in the ordinary course of nature, giving us sports of various kinds. These critical periods, however, are not unwelcome, since skilful cultivators can take advantage of them. In this very field much has been accomplished. An attentive study of the sagacious work done by Thomas Andrew Knight shows to what extent this can be done. But we must confess that it would be absolutely impossible to predict with certainty how long or how short would be the time before new cereals or acceptable equivalents for them would be provided. Upheld by the confidence which I have in the intelligence, ingenuity, and energy of our experiment stations, I may say that the time would not probably exceed that of two generations of our race, or half a century.

In now laying aside our hypothetical illustration, I venture to ask why it is that our experiment stations, and other institutions dealing with plants and their improvement, do not undertake investigations like those which I have sketched? Why are not some of the grasses other than our present cereals studied with reference to their adoption as food grains? One of these species will naturally suggest itself to you all—namely, the wild rice of the lakes. Observations have shown that, were it not for the difficulty of harvesting these grains, which fall too easily when they are ripe, they might be utilized. But attentive search might find or educe some variety of *Zizania*, with a more persistent grain and a better yield. There are two of our seashore grasses which have excellent grains, but are of small yield. Why are not these, or better ones which might be suggested by observation, taken in hand?

The reason is plain. We are all content to move along in lines of least resistance, and are disinclined to make a fresh start. It is merely leaving well enough alone, and so far as the cereals are concerned it is indeed well enough. The generous grains of modern varieties of wheat and barley compared with the well-preserved charred vestiges found in Greece by Schliemann, and in the lake-dwellings, are satisfactory in every respect. Improvements, however, are making in many directions; and in the cereals we now have, we possess far better and more satisfactory material for further improvement both in quality and as regards range of distribution than we could reasonably hope to have from other grasses.

From the cereals we may turn to the interesting groups of plants comprised under the general term

II. VEGETABLES.

Under this term it will be convenient for us to include all plants which are employed for culinary purposes, or for table use, such as salads and relishes.

The potato and sweet potato, the pumpkin and squash, the red or capsicum peppers, and the tomato, are of American origin.

All the others are, most probably, natives of the Old World. Only one plant coming in this class has been derived from Southern Australasia—namely, New Zealand spinach (*Tetragonia*).

Among the vegetables and salad-plants longest in cultivation we may enumerate the following: turnip, onion, cabbage, purslane, the large bean (Faba), chick-pea, lentil, and one species of pea (garden-pea). To these an antiquity of at least 4000 years is ascribed.

Next to these, in point of age, come the radish, carrot, beet, garlic, garden-cress, and celery, lettuce, asparagus, and the leek. Three or four leguminous seeds are to be placed in the same category, as are also the black peppers.

Of more recent introduction the most prominent are: the parsnip, oyster-plant, parsley, artichoke, endive, and spinach.

From these lists I have purposely omitted a few which belong exclusively to the tropics, such as certain yams.

The number of varieties of these vegetables is astounding. It is, of course, impossible to discriminate between closely allied varieties which have been introduced by gardeners and seedsmen under different names, but which are essentially identical, and we must therefore have recourse to a conservative authority, Vilmorin, from whose work a few examples have been selected. The varieties which he accepts are sufficiently well distinguished to admit of description, and in most instances of delineation, without any danger of confusion. The potato has, he says, innumerable varieties, of which he accepts forty as easily distinguishable and worthy of a place in a general list; but he adds also a list, comprising, of course, synonyms, of thirty-two French, twenty-six English, nineteen American, and eighteen German varieties. The following numbers speak for themselves, all being selected in the same careful manner as those of the potato: celery more than twenty; carrot more than thirty; beet, radish, and potato, more than forty; lettuce and onion more than fifty; turnip more than seventy; cabbage, kidney-bean, and garden pea, more than one hundred.

The amount of horticultural work which these numbers represent is enormous. Each variety established as a race (that is, a variety which comes true to seed) has been evolved by the same sort of patient care and waiting which we have seen is necessary in the case of cereals, but the time of waiting has not been as a general thing so long.

In the case of the cabbage there are important morphological changes like those to which Prof. Bailey has called attention in the case of the tomato. Suppose we are strolling along the beach at some of the seaside resorts of France, and should fall in with this coarse cruciferous plant, with its sprawling leaves and strong odour. Would there be anything in its appearance to lead us to search for its hidden merit as a food-plant? What could we see in it which would give it a preference over a score of other plants at our feet? Again, suppose we are journeying in the high lands of Peru, and should meet with a strong-smelling plant of the nightshade family, bearing a small irregular fruit, of sub-acid taste and of peculiar flavour. We will further imagine that the peculiar taste strikes our fancy, and we conceive that the plant has possibilities as a source of food. We should be led by our knowledge of the potato, probably a native of the same region, to think that this allied plant might be safely transferred to a northern climate, but would there be promise of enough future usefulness, in such a case as this, to warrant our carrying the plant north as an article of food? Suppose, further, we should ascertain that the fruit in question was relished not only by the natives of its home, but that it had found favour among the tribes of South Mexico and Central America, and had been cultivated by them until it had attained a large size; should we be strengthened in our venture? Let us go one step further still. Suppose that, having decided upon the introduction of the plant, and having urged everybody to try it, we should find it discarded as a fruit, but taking a place in gardens as a curiosity under an absurd name, or as a basis for preserves and pickles; should we not look upon our experiment in the introduction of this new plant as a failure? This is not a hypothetical case.

The tomato, the plant in question, was cultivated in Europe as long ago as 1554; it was known in Virginia in 1781 and in the Northern States in 1785; but it found its way into favour slowly, even in this land of its origin. A credible witness states that in Salem it was almost impossible to induce people to eat or even taste of the fruit. And yet, as you are well aware, its present cultivation on an enormous scale in Europe and this country is scarcely sufficient to meet the increasing demand.

Before asking specifically in what direction we shall look for new vegetables, I must be pardoned for calling attention, in passing, to a very few of the many which are already in limited use in Europe and this country, but which merit a wider employment. Cardon, or cardoon; celeriac, or turnip-rooted celery; fetticus, or corn-salad; martynia; salsify; sea-kale; and numerous small salads, are examples of neglected treasures of the vegetable garden.

The following, which are even less known, may be mentioned as fairly promising;—

(1) *Arracacia esculenta*, called Arracacha, belonging to the parsley family. It is extensively cultivated in some of the northern States of South America. The stems are swollen near

the base, and produce tuberous enlargements filled with an excellent starch. Although the plant is of comparatively easy cultivation, efforts to introduce it into Europe have not been successful, but it is said to have found favour in both the Indies, and may prove useful in our Southern States.

(2) *Ullucus* or Ollucus, another tuberous-rooted plant from nearly the same region, but belonging to the beet or spinach family. It has produced tubers of good size in England, but they are too waxy in consistence to dispute the place of the better tubers of the potato. The plant is worth investigating for our hot dry lands.

(3) A tuber-bearing relative of our common hedge-nettle, or *Stachys*, is now cultivated on a large scale at Crosnes, in France, for the Paris market. Its name in Paris is taken from the locality where it is now grown for use. Although its native country is Japan, it is called by some seedsmen Chinese artichoke. At the present stage of cultivation, the tubers are small and are rather hard to keep, but it is thought "that both of these defects can be overcome or evaded." Experiments indicate that we have in this species a valuable addition to our vegetables.

We must next look at certain other neglected possibilities.

Dr. Edward Palmer, whose energy as a collector and acuteness as an observer are known to you all, has brought together very interesting facts relative to the food-plants of our North American aborigines. Among the plants described by him there are a few which merit careful investigation. Against all of them, however, there lie the objections mentioned before, namely:—

(1) The long time required for their improvement, and

(2) The difficulty of making them acceptable to the community, involving

(3) The risk of total and mortifying failure.

In 1854 the late Prof. Gray called attention to the remarkable relations which exist between the plants of Japan and those of our eastern coast. You will remember that he not only proved that the plants of the two regions had a common origin, but also emphasized the fact that many species of the two countries are almost identical. It is to that country which has yielded us so many useful and beautiful plants that we turn for new vegetables to supplement our present food resources. One of these plants—namely, *Stachys*—has already been mentioned as promising. There are others which are worth examination and perhaps acquisition.

One of the most convenient places for a preliminary examination of the vegetables of Japan is at the railroad stations on the longer lines—for instance, that running from Tokio to Kobe. For native consumption there are prepared luncheon boxes of two or three stories, provided with the simple and yet embarrassing chopsticks. It is worth the shock it causes one's nerves to invest in these boxes and try the vegetable contents. The bits of fish, flesh, and fowl which one finds therein can be easily separated and discarded, upon which there will remain a few delicacies. The pervading odour of the box is that of aromatic vinegar. The generous portion of boiled rice is of excellent quality, with every grain well softened and distinct, and this without anything else would suffice for a tolerable meal. In the boxes which have fallen under my observation there were sundry boiled roots, shoots, and seeds which were not recognizable by me in their cooked form. Prof. Georgeson, formerly of Japan, has kindly identified some of these for me, but he says, "There are doubtless many others used occasionally."

One may find sliced lotus roots, roots of large burdock, lily bulbs, shoots of ginger, pickled green plums, beans of many sorts, boiled chestnuts, nuts of the gingko tree, pickled greens of various kinds, dried cucumbers, and several kinds of seaweeds. Some of the leaves and roots are cooked in much the same manner as beet-roots and beet-leaves are by us, and the general effect is not unappetizing. The boiled shoots are suggestive of only the tougher ends of asparagus. On the whole, I do not look back on Japanese railway luncheons with any longing which would compel me to advocate the indiscriminate introduction of the constituent vegetables here.

But when the same vegetables are served in native inns, under more favourable culinary conditions, without the flavour of vinegar and of the pine wood of the luncheon boxes, they appear to be worthy of a trial in our horticulture, and I therefore deal with one or two in greater detail.

Prof. Georgeson, whose advantages for acquiring a knowledge of the useful plants of Japan have been unusually good, has placed me under great obligations by communicating certain facts regarding some of the more promising plants of Japan which are not now used here. It should be said that several of these plants have already attracted the notice of the Agricultural Department in this country.

The soy bean (*Glycine hispida*). This species is known here to some extent, but we do not have the early and best varieties. These beans replace meat in the diet of the common people.

Mucuna (*Mucuna capitata*) and dolichos (*Dolichos cultratus*) are pole beans possessing merit.

Dioscorea. There are several varieties with palatable roots. Years ago one of these was spoken of by the late Dr. Gray as possessing "excellent roots, if one could only dig them."

Colocasia antiquorum has tuberous roots, which are nutritious.

Conophallus Konjak has a large bulbous root, which is sliced, dried, and beaten to a powder. It is an ingredient in cakes.

Aralia cordata is cultivated for the shoots, and used as we use asparagus.

Œnanthe stolonifera and *Cryptotænia canadensis* are palatable salad plants, the former being used also as greens.

III. FRUITS.

Botanically speaking, the cereal grains of which we have spoken are true fruits—that is to say, are ripened ovaries, but for all practical purposes they may be regarded as seeds. The fruits of which mention is now to be made are those commonly spoken of in our markets as fruits.

First of all, attention must be called to the extraordinary changes in the commercial relations of fruits by two direct causes—

(1) The canning industry, and

(2) Swift transportation by steamers and railroads.

The effects of these two agencies are too well known to require more than this passing mention. By them the fruits of the best fruit-growing countries are carried to distant lands in quantities which surprise all who see the statistics for the first time. The ratio of increase is very startling. Take, for instance, the figures given by Mr. D. Morris, at the time of the great Colonial and Indian Exhibition in London. Compare double decades of years—

	£
1845	886,888
1865	3,185,984
1885	7,587,523

In the Colonial Exhibition at London, in 1886, fruits from the remote colonies were exhibited under conditions which proved that, before long, it may be possible to place such delicacies as the cherimoyer, the sweet-cup, sweet-sop, rambutan, mango, and mangosteen, at even our most northern seaports. Furthermore, it seems to me likely that, with an increase in our knowledge with regard to the microbes which produce decay, we may be able to protect the delicate fruits from injury for any reasonable period. Methods which will supplement refrigeration are sure to come in the very near future, so that even in a country so vast as our own, the most perishable fruits will be transported through its length and breadth without harm.

The canning industry and swift transportation are likely to diminish zeal in searching for new fruits, since, as we have seen in the case of the cereals, we are prone to move in lines of least resistance, and leave well enough alone.

To what extent are our present fruits likely to be improved? Even those who have watched the improvement in the quality of some of our fruits, like oranges, can hardly realize how great has been the improvement within historic times in the character of certain pears, apples, and so on.

The term historic is used advisedly, for there are pre-historic fruits which might serve as a point of departure in the consideration of the question. In the ruins of the lake-dwellings in Switzerland, charred apples have been found, which are in some cases plainly of small size, hardly equalling ordinary crab apples. But, as Dr. Sturtevant has shown, in certain directions there has been no marked change of type—the change is in quality.

In comparing the earlier descriptions of fruits with modern accounts, it is well to remember that the high standards by which fruits are now judged are of recent establishment. Fruits which would once have been esteemed excellent would to-day be passed by as unworthy of regard.

It seems probable that the list of seedless fruits will be materially lengthened, provided our experimental horticulturists make use of the material at their command. The common fruits which have very few or no seeds are the banana, pineapple, and certain oranges. Others mentioned by Mr. Darwin as well known are the bread-fruit, pomegranate, arazole or Neapolitan medlar, and date-palms. In commenting upon these fruits, Mr. Darwin says that most horticulturists "look at the great size and anomalous development of the fruit as the cause, and sterility as the result," but he holds the opposite view as more probable—that is, that the sterility, coming about gradually, leaves free for other growth the abundant supply of building material which the forming seed would otherwise have. He admits, however, that "there is an antagonism between the two forms of reproduction, by seeds and by buds, when either is carried to an extreme degree, which is independent of any incipient sterility."

Most plant-hybrids are relatively infertile, but by no means wholly sterile. With this sterility there is generally augmented vegetative vigour, as shown by Nägeli. Partial or complete sterility, and corresponding luxuriance of root, stem, leaves, and flower may come about in other obscure ways, and such cases are familiar to botanists. Now, it seems highly probable that, either by hybridizing directed to this special end, or by careful selection of forms indicating this tendency to the correlated changes, we may succeed in obtaining important additions to our seedless or nearly seedless plants. Whether the ultimate profit would be large enough to pay for the time and labour involved is a question which we need not enter into; there appears to me no reasonable doubt that such efforts would be successful. There is no reason in the nature of things why we should not have strawberries without the so-called seeds; blackberries and raspberries, with only delicious pulp; and large grapes as free from seeds as the small ones which we call "currants," but which are really grapes from Corinth.

These, and the coreless apples and pears of the future, the stoneless cherries and plums, like the common fruits beforementioned, must be propagated by bud-division, and be open to the tendency to diminished strength said to be the consequence of continued bud-propagation. But this bridge need not be crossed until we come to it. Bananas have been perpetuated in this way for many centuries, and pineapples since the discovery of America, so that the borrowed trouble alluded to is not threatening.

It is absolutely necessary to recollect that, in most cases, variations are slight. Dr. Masters and Mr. Darwin have called attention to this, and have adduced many illustrations, all of which show the necessity of extreme patience and caution. The general student curious in such matters can have hardly any task more instructive than the detection of the variations in such common plants as the blueberry, the wild cherry, or the like. It is an excellent preparation for a practical study of the variations in our wild fruits suitable for selection.

It was held by the late Dr. Gray that the variations in nature by which species have been evolved were led along useful lines —a view which Mr. Darwin regretted he could not entertain. However this may be, all acknowledge that, by the hand of the cultivator, variations can be led along useful lines; and, furthermore, the hand which selects must uphold them in their unequal strife. In other words, it is one thing to select a variety, and another to assist it in maintaining its hold upon existence. Without the constant help of the cultivator who selects the useful variety, there comes a reversion to the ordinary specific type which is fitted to cope with its surroundings.

I think you can agree with me that the prospect for new fruits and for improvements in our established favourites is fairly good.

IV. Timbers and Cabinet Woods.

Can we look for new timbers and cabinet woods? Comparatively few of those in common use are of recent introduction. Attempts have been made to bring into great prominence some of the excellent trees of India and Australia which furnish wood of much beauty and timber of the best quality. A large proportion of all the timbers of the South Seas are characterized by remarkable firmness of texture and high specific gravity. The same is noticed in many of the woods of the Indies. A few of the heavier and denser sorts, like Jarrah, of West Australia, and Sabicu of the Caribbean Islands, have met with deserved favour in England, but the cost of transportation militates against them. It is a fair question whether, in certain parts of our country, these trees, and others which can be utilized for veneers, may not be cultivated to advantage. Attention should be again called to the fact that many plants succeed far better in localities which are remote from their origin, but where they find conditions substantially like those which they have left. This fact, to which we must again refer in detail with regard to certain other classes of plants, may have some bearing upon the introduction of new timber trees. Certain drawbacks exist with regard to the timber of some of the more rapidly growing hard-wood trees which have prevented their taking a high place in the scale of values in mechanical engineering.

One of the most useful soft-wooded trees in the world is the Kauri. It is restricted in its range to a comparatively small area in the North Island of New Zealand. It is now being cut down with a recklessness which is as prodigal and shameful as that which has marked our own treatment of forests here. It should be said, however, that this destruction is under protest; in spite of which it would seem to be a question of only a few years when the great Kauri groves of New Zealand will be a thing of the past. Our energetic Forest Department has on its hands problems just like this which perplexes one of the new lands of the South. The task in both cases is double: to preserve the old treasures and to bring in new.

There is no department of economic botany more promising in immediate results than that of arboriculture.

V. Vegetable Fibres.

The vegetable fibres known to commerce are either plant hairs, of which we take cotton as the type, or filaments of bast-tissue, represented by flax. No new plant hairs have been suggested which can compete in any way for spinning with those yielded by the species of Gossypium, or cotton, but experiments more or less systematic and thorough are being carried on with regard to the improvement of the varieties of the species. Plant hairs for the stuffing of cushions and pillows need not be referred to in connection with this subject.

Countless sorts of plants have been suggested as sources of good bast-fibres for spinning and for cordage, and many of these make capital substitutes for those already in the factories. But the questions of cheapness of production, and of subsequent preparation for use, have thus far militated against success. There may be much difference between the profits promised by a laboratory experiment and those resulting from the same process conducted on a commercial scale. The existence of such differences has been the rock on which many enterprises seeking to introduce new fibres have been wrecked.

In dismissing this portion of our subject it may be said that a process for separating fine fibres from undesirable structural elements and from resin-like substances which accompany them is a great desideratum. If this were supplied, many new species would assume great prominence at once.

VI. Tanning Materials.

What new tanning materials can be confidently sought for? In his "Useful Native Plants of Australia," Mr. Maiden describes over thirty species of "wattles" or acacias, and about half as many eucalypts, which have been examined for the amount of tanning material contained in the bark. In all, eighty-seven Australian species have been under examination. Besides this, much has been done looking in the same direction at the suggestion and under the direction of Baron von Mueller, of Victoria. This serves to indicate how great is the interest in this subject, and how wide is the field in our own country for the introduction of new tanning plants.

It seems highly probable, however, that artificial tanning substances will at no distant day replace the crude matters now employed.

VII. Resins, &c.

Resins, oils, gums, and medicines from the vegetable kingdom would next engage our attention if they did not seem rather too technical for this occasion, and to possess an interest on the whole somewhat too limited. But an allied substance may serve to represent this class of products and indicate the drift of present research.

India Rubber.—Under this term are included numerous substances which possess a physical and chemical resemblance to each other. An Indian Ficus, the early source of supply, soon became inadequate to furnish the quantity used in the arts even when the manipulation of rubber was almost unknown. Later supplies came from *Hevea* of Brazil, generally known as Para rubber, and from *Castilloa*, sometimes called Central American rubber, and from *Manihot Glaziovii*, Ceara rubber. Not only are these plants now successfully cultivated in experimental gardens in the tropics, but many other rubber-yielding species have been added to the list. The Landolphias are among the most promising of the whole: these are the African rubbers. Now in addition to these, which are the chief source of supply, we have *Willughbeia*, from the Malayan Peninsula, *Leuconotis*, *Chilocarpus*, *Alstonia*, *Forsteronia*, and a species of a genus formerly known as *Urostigma*, but now united with *Ficus*. These names, which have little significance as they are here pronounced in passing, are given now merely to impress upon our minds the fact that the sources of a single commercial article may be exceedingly diverse. Under these circumstances search is being made not only for the best varieties of these species but for new species as well.

There are few excursions in the tropics which possess greater interest to a botanist who cares for the industrial aspects of plants than the walks through the Gardens at Buitenzorg in Java and at Singapore. At both these stations the experimental gardens lie at some distance from the great Gardens which the tourist is expected to visit, but the exertion well repays him for all discomfort. Under the almost vertical rays of the sun, are here gathered the rubber-yielding plants from different countries, all growing under conditions favourable for decisions as to their relative value. At Buitenzorg a well-equipped laboratory stands ready to answer practical questions as to quality and composition of their products, and year by year the search extends.

I mention this, not as an isolated example of what is being accomplished in commercial botany, but as a fair illustration of the thoroughness with which the problems are being attacked. It should be further stated that at the Garden in question assiduous students of the subject are eagerly welcomed, and are provided with all needed appliances for carrying on technical, chemical, and pharmaceutical investigations. Therefore I am justified in saying that there is every reason for believing that in the very near future new sources of our most important products will be opened up, and new areas placed under successful cultivation.

At this point, attention must be called to a very modest and convenient hand-book on the "Commercial Botany of the Nineteenth Century," by Mr. Jackson, of the Botanical Museum attached to the Royal Gardens, Kew, which not only embodies a great amount of well-arranged information relative to the new useful plants, but is, at the same time, a record of the existing state of things in all these departments of activity.

VIII. FRAGRANT PLANTS.

Another illustration of our subject might be drawn from a class of plants which repays close study from a biological point of view—namely, those which yield perfumes.

In speaking of the future of our fragrant plants we must distinguish between those of commercial value and those of purely horticultural interest. The former will be less and less cultivated in proportion as synthetic chemistry by its manufacture of perfumes replaces the natural by the artificial products; for example, coumarin, vanillin, nerolin, heliotropin, and even oil of wintergreen.

When, however, one has seen that the aromatic plants of Australia are almost free from attacks of insects and fungi, and has learned to look on the impregnating substances in some cases as protective against predatory insects and small foes of all kinds, and in others as fungicidal, he is tempted to ask whether all the substances of marked odour which we find in certain groups of plants may not play a similar *rôle*.

It is a fact of great interest to the surgeon that in many plants there is associated with the fragrant principle a marked antiseptic or fungicidal quality; conspicuous examples of this are afforded by species of *Eucalyptus*, yielding eucalyptol, *Styrax*, yielding styrone, *Thymus*, yielding thymol. It is interesting to note, too, that some of these most modern antiseptics were important constituents in the balsamic vulneraries of the earliest surgery.

Florists' plants and the floral fashions of the future constitute an engaging subject, which we can touch only lightly. It is reasonably clear that while the old favourite species will hold their ground in the guise of improved varieties, the new introductions will come in the shape of plants with flowering branches which retain their blossoms for a somewhat long period, and especially those in which the flowers precede the leaves. In short, the next real fashion in our gardens is probably to be the flowering shrub and flowering tree, like those which are such favourites in the country from which the Western world has gladly taken the gift of the chrysanthemum.

Twice each year, of late, a reception has been held by the Emperor and Empress of Japan. The receptions are in autumn and in the spring. That in the autumn, popularly known as the Emperor's reception, has for its floral decorations the myriad forms of the national flower, the chrysanthemum; that which is given in spring, the Empress's reception, comes when the cherry blossoms are at their best. One has little idea of the wealth of beauty in masses of flowering shrubs and trees, until he has seen the floral displays in the Imperial Gardens and the Temple grounds in Tokio.

CONCLUSION.

Lack of time renders it impossible to deal with the questions which attach themselves to our main question, especially as to the limits of effect which cultivation may produce. We cannot touch the problem of inheritance of acquired peculiarities, or the manner in which cultivation predisposes the plant to innumerable modifications. Two of these modifications may be mentioned in passing, because they serve to exemplify the practical character of our subject.

Cultivation brings about in plants very curious morphological changes. For example, in the case of a well-known vegetable the number of metamorphosed type-leaves forming the ovary is two, and yet under cultivation the number increases irregularly until the full number of units in the type of the flower is reached. Prof. Bailey, of Cornell, has called attention to some further interesting changes in the tomato, but the one mentioned suffices to illustrate the direction of variation which plants under cultivation are apt to take. Monstrosities are very apt to occur in cultivated plants, and under certain conditions may be perpetuated in succeeding generations, thus widening the field from which utilizable plants may be taken.

Another case of change produced by cultivation is likewise as yet wholly unexplained, although much studied—namely, the mutual interaction of scion and stock in grafting, budding, and the like. It is probable that a further investigation of this subject may yet throw light on new possibilities in plants.

We have now arrived at the most practical question of all, namely—

In what way can the range of commercial botany be extended? In what manner, or by what means, can the introduction of new species be hastened?

It is possible that some of you are aware of the great amount of uncoordinated work which has been done and is now in hand in the direction of bringing in new plants.

The competition between the importers of new plants is so great both in the Old World and the New that a very large proportion of the species which would naturally commend themselves for the use of florists, for the adornment of greenhouses, or for commerical ends, have been at one time or another brought before the public or are being accumulated in stock. The same is true, although to a less extent, with regard to useful vegetables and fruit. Hardly one of those which we can suggest as desirable for trial has not already been investigated in Europe or this country, and reported on. The pages of our chemical, pharmaceutical, medical, horticultural, agricultural and trade journals, especially those of high grade, contain a wealth of material of this character.

But what is needed is this: that the promising plants should be systematically investigated under exhaustive conditions. It is not enough that an enthusiast here, or an amateur there, should give a plant a trial under imperfectly understood conditions, and then report success or failure. The work should be thorough, and every question answered categorically, so that we might be placed in possession of all the facts relative to the object experimented upon. But such an undertaking requires the co-operation of many different agencies. I shall venture to mention some of these.

In the first place, Botanic Gardens amply endowed for research. The Arnold Arboretum, the Shaw Garden, and the Washington Experimental Garden, are American illustrations of what is needed for this purpose. University gardens have their place in instruction, but cannot wisely undertake this kind of work.

In the second place, Museums and Laboratories of Economic Botany. Much good work in this direction has been done in this country by the National Museum and by the department in charge of the investigation of new plants. We need institutions like those at Kew in England, and at Buitenzorg in Java, which keep in close touch with all the world. The founding of an establishment on a scale of magnitude commensurate with the greatness and needs of our country is an undertaking which waits for some one of our wealthy men.

In the third place, Experiment Stations. These may, within the proper limits of their sphere of action, extend the study of plants beyond the established varieties to the species, and beyond the species to equivalent species in other genera. It is a matter of regret that so much of the energy displayed in these stations in this country, and we may say abroad, has not been more economically directed.

Great economy of energy must result from the recent change by which co-ordination of action is assured. The influence which the stations must exert on the welfare of our country and the development of its resources is incalculable.

In the last place, but by no means least, the co-operation of all who are interested in scientific matters, through their observation of isolated and associated phenomena connected with plants of supposed utility, and by the cultivation of such plants by private individuals, unconnected with any State, Governmental, or academic institutions.

By these agencies, wisely directed and energetically employed, the domains of commercial and industrial botany will be enlarged. To some of the possible results in these domains, I have endeavoured to call your attention.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. BONNEY will begin a course of about sixty lectures on geology at University College, London, on Tuesday, October 6, at noon, and a course of about eighteen lectures on geology for engineering students, on Monday, October 12, at 2 p.m. A class for students preparing for the B.Sc. degree in the University of London will meet on October 6 at 2 p.m.

THE prizes to the students at the medical school of St. Thomas's Hospital will be distributed to-day by Sir G. M. Humphry, F.R.S.

LECTURES will be delivered in Gresham College, Basinghall Street, E.C., on October 6, 7, 8, and 9, by Dr. E. Symes Thompson, Gresham Professor of Medicine, on influenza and its results.

SEVERAL series of lectures for which the Salop County Council has made arrangements have been begun. They are on chemistry, botany, geology, agricultural chemistry, management of stock, insect pests and crop diseases, mechanics, and principles of agriculture, and are being given in various parts of the county. Most of them are being delivered in connection with the Oxford University Extension Scheme.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 21.—M. Duchartre in the chair.—Admiral Mouchez made some remarks on the second volume of the Paris Observatory Star Catalogue, presented to the Academy. The Catalogue contains stars between the right ascensions 6h. and 12h., and about 500,000 observations made at Paris during the last fifty years have been utilized in its construction.—On the colour sensations excited in one eye by coloured light which illuminates the retina of the other, by M. A. Chauveau. From the experiments described it appears that the excitation of one retina by coloured light influences, not only the optic nerves of this retina, but also those of the opposite side, so that the latter are able to awaken the sensation of the colour employed whilst the excited retina only sees the complementary colour. Thus, if a white surface be observed for a short time through a bit of coloured glass, using only one eye, and screening the other, when the glass is taken away the white ground appears to be tinted with a colour complementary to that of the glass. This is an old experiment, but the point is that if the first eye be closed and the screened eye opened the white surface appears to be tinted with the same colour as the glass.—Observations of the asteroid discovered by Charlois on August 28, made with the *coudé* equatorial of Algiers Observatory, by M. F. Sy. Observations for position were made on August 31 and September 7.—Observations of Wolf's comet (1884 *e* III.) made with the *coudé* equatorial (0·36m. aperture) of Lyons Observatory, by M. G. Le Cadet. Observations for position were made on September 9, 10, 11, and 12.—On the partial eclipse of Jupiter's first satellite by the shadow of the second, by M. J. J. Landerer. This phenomenon occurred on August 14.—The metamorphoses of *Acridium peregrinum*, Oliv., by M. Charles Brongniart. The author has specially observed that locusts undergo various colour changes at different stages of their existence.—On the grafting of underground portions of plants, by M. Lucien Daniel.

THE ICE AGE IN NORTH AMERICA.

The Ice Age in North America, and its Bearings upon the Antiquity of Man. By G. Frederick Wright, D.D., &c. With an Appendix on "The Probable Cause of Glaciation," by Warren Upham, F.G.S.A. With many new Maps and Illustrations. (London: Kegan Paul, Trench, Trübner, and Co., Limited, 1890.)

SWITZERLAND has been called the playground of Europe. The glacial epoch occupies a similar position in geology. Here the student, wearied with the precision of palæontology or of mineralogy, may revel in dreams of omnipotent glaciers, wrap himself in ice sheets, throw mental somersaults, swallow self-contradictory arguments, and be as blind to unpleasant facts as was Nelson at Copenhagen, when he put the telescope to his useless eye, and "spoke disrespectfully" of the signal of recall. To any sarcastic historian of the progress of geology, the literature of ice and its effects will be a boon, since it is so rich in unsound inductions and unstable hypotheses.

Dr. Wright's book, however, is, on the whole, a favourable exception to this general rule. Passages, no doubt, may be found here and there, to which exception might be taken—notably to his remarks on the subject of cirques, in which he regards with favour opinions which are hard to reconcile with expressions in other parts of the book, and rest largely on an erroneous statement—namely, that cirques "are confined to glaciated regions," and "as a rule . . . occupy positions where glaciers first appear." Still, in general his conclusions are supported by facts, very clearly and carefully described, so that we feel, even if occasionally not quite convinced, that his view is worthy of careful and respectful consideration.

But in the matter of ice the subject is long, and our space is brief. It will be better to abstain from criticism of details and give a short outline of those parts of Dr. Wright's book which will be of most interest to readers on this side of the Atlantic. As he states in his preface, his work deals not only with the Ice Age in North America, but also with the whole subject of the Glacial Period. So in its earlier part a considerable space is allotted to glaciers in general and their characteristics; in its later, to the effects of the Glacial Period in other parts of the world, its cause, its date, and its relation to the history of man. These, however, we shall pass over, and confine ourselves to the section dealing with glacial action on the North American continent.

After a sketch of the existing glaciers on the Pacific coast, Dr. Wright gives the results of a study of the Muir glacier in latitude 58° 50′, by the side of which a small party, of which he was a member, camped out for a month. This glacier is about a mile wide where it comes down to the sea, terminating in ice cliffs 300 feet, and sometimes a little above 400 feet in height. The rise inland is gradual—perhaps about 100 feet per mile—and the main body of the glacier occupies a vast amphitheatre, with diameters ranging from 30 to 40 miles. From a number of observations it appeared that the stream of ice entered the inlet, where the cross section was about five million square feet (5000 feet wide by 1000 deep), at an average rate of 40 feet a day (70 feet in the centre and 10 near the margin). It was, however, evident that this glacier, for some time past, had been retreating; indeed, fresh striations and *débris* could be traced to more than 2500 feet above its present surface. Dr. Wright also found below the end of the ice the dead stumps of a forest of cedar trees, erect, and rooted in a clayey soil, but buried beneath glacial gravel. Probably this was deposited by streams, flowing from the advancing ice, which afterwards overrode the mass.

Dr. Wright estimates the amount of sediment which is now being washed down from the basin of the Muir Glacier as equal to nearly one-third of an inch per annum over the total area (1200 square miles) which it occupies. In regard to the vexed question of the excavatory powers of glaciers, Dr. Wright expresses himself, as a rule, cautiously, ascribing to them the formation of true rock-basins under favourable circumstances, but laying stress upon the fact that, in the lower part of their course, where they are beginning to spread out over the lowlands, they can pass, as in the case mentioned above, over quite incoherent materials, without disturbing them. It also seems to follow from his remarks that he regards glaciers as agents of abrasion rather than of erosion, in which we have no doubt he is correct. As another indication of his general caution and candour, we may note that he is careful to point out that striated stones and rock surfaces do not always prove the former presence of a glacier, and may not even have been produced by the action of ice.

A large part of the book is devoted, as a matter of course, to a description of the glaciated area in North America. The boundary of this, as Dr. Wright explains, is sometimes distinctly marked by a terminal moraine, at others it is less definite, being only vaguely indicated by scattered *débris.* But in his opinion—and here he expresses the opinion of the majority of American geologists—there was a time when a large part of Northern America east of the Rocky Mountains was buried beneath a mass of ice. There is, indeed, a driftless area in Wisconsin, which may have formed a kind of *jardin* on a gigantic scale, in this huge *mer de glace*, but, speaking generally, the whole region of the great lakes was covered by an ice-sheet which came down to the sea at Long Island and traversed the northern part of Pennsylvania; thence its irregular frontal margin can be traced to the south-west, until, in the valley of the Mississippi, it reaches almost as far south as the 37th parallel of latitude. Of the various indications of this vanished ice-sheet, the smoothed and striated surfaces of rock, the moraines and boulder clays, the "kames" and "drumlins," Dr. Wright gives careful descriptions and illustrations, usually taken from photographs, so that the evidence is presented as clearly as is possible to the reader. To the last-named phenomena—the "kames" and "drumlins"—and some curious hollows which he calls "kettle-holes," Dr. Wright devotes much attention. The first he regards as indicative of lines of drainage in the closing stage of the Ice Age; the second, as early terminal moraines, modified in shape by the subsequent passage of the ice over them, and so anterior in date to the kames. The kettle-holes occur among morainic deposits, and are thus explained:—As the ice is retreating, a mass of it may be insulated; as this melts, the superincumbent material tends to slip towards the edges, and thus to form a ring of *débris*, by which, after the ice has disappeared, a hollow is inclosed. Dr. Wright also adopts the opinion, maintained by Prof. Claypole, the late Prof. H. C. Lewis, and others, that one effect of the advance of this great mass of ice was to obstruct the flow of all rivers which take a northerly course, and thus to convert their valleys into lakes.

But into a discussion of this interesting question, and of the cause of the glacial epoch, to which a considerable space is devoted, we must not now enter. We must also pass over the questions relating to the date of the glacial epoch and its relation to the first appearance of men, merely stating that Dr. Wright inclines to regard the latter as pre-glacial, but the former as less remote than is generally supposed. It must suffice to say that he appears to be a careful observer, and generally a cautious reasoner, though slightly too prone to quote the remarks of others without due criticism; so that, on the whole, his book presents us with a good summary of the results of investigations into the glacial geology of North America, and will be valuable for purposes of reference on this side of the Atlantic.

T. G. Bonney.

THE TOTAL REFLECTOMETER AND THE REFRACTOMETER FOR CHEMISTS.

Das Totalreflectometer und das Refractometer für Chemiker, ihre Verwendung in der Krystalloptik und zur Untersuchung der Lichtbrechung von Flüssigkeiten. Von Dr. C. Pulfrich, Privatdocenten an der Universität Bonn, und Assistenten des physikalischen Instituts. With 4 Lithographic Plates and 45 Figures in the Text. (Leipzig: W. Engelmann, 1890.)

THIS book contains an exhaustive account of one of the latest devices in physical optics for investigating the refractive power of uniaxial and biaxial crystals. The idea of making use of the principle of total reflection for this purpose is not new. Wollaston, at the beginning of the century, brought forward a method in which the crystal plate under examination was attached to a glass prism; but, owing to the experimental difficulties involved in this process, it met with little practical application. The instrument constructed by Kohlrausch in 1878, in which the crystal plate was immersed in a strongly refractive liquid, was a distinct advance, and has been much used. Within the last ten years, also, Wollaston's apparatus has been considerably improved by Fussner and Liebisch. Both these instruments, however, have still many inconveniences, and it is the claim of the author that the method which he has devised, and which forms the subject of the present work, is free from these.

To give some idea of this method, without entering into practical details, it will be sufficient to state that it consists essentially in the replacement of the prism of the Wollaston instrument by a glass cylinder, to the upper plane surface of which the crystal plate is attached. The cylinder can be rotated about its long axis, so that the refractive phenomena in all azimuths can be observed. This is the distinguishing feature which forms the chief advantage of the new method. Thus, by illuminating the crystal plate from the side at grazing incidence, and slowly rotating the cylinder, the whole extent of the limiting curves of total reflection comes under observation. By a special method of illumination from all sides the limiting curves may be received on a screen beneath the cylinder and made visible to a number of observers; *e.g.* in the case of a uniaxial crystal the appearance on the screen will be the sectional curves of the wave-surface, a circle and an ellipse corresponding to the ordinary and extraordinary rays.

The method was first suggested by the author four years ago. The object of the present work is to give a complete account of the series of measurements and observations which have been made with the instrument since that time with a view to testing its usefulness and trustworthiness. After some preliminary observations on the theoretical principles involved in the method of total reflection, the author gives a detailed description of the construction of the new instrument and the methods of observation by which it is possible in a single crystal section to ascertain the position of the axes of elasticity, to measure the optic axial angle for different colours, and to determine the principal refractive indices. Of special interest is the section on the appearances in the direction of the optic axes of biaxial crystals. Observations made on a plate of asparagine, cut parallel to the optic axial plane, showed distinctly the effects due to the internal and external conical refraction, thus supplementing Lloyd's experiments in demonstrating the general correctness of the Fresnel wave-surface. The last section of the book deals with the refraction of liquids, and contains a description of the refractometer for chemists, which is a simplified form of the total reflectometer, in which a prism replaces the cylinder. Altogether, a perusal of the work leaves the impression that the invention of this ingenious and yet comparatively simple method for investigating the refractive power of doubly refractive media marks a decided advance in physical science; and the author appears to have quite substantiated his claim to have made the total reflection method, which has long been recognized as theoretically the most promising, also a thoroughly practical one.

G. T. P.

A WEATHER RECORD OF THE FOURTEENTH CENTURY.

Consideraciones temperiei pro 7 annis, per Magistrem Wilhelmum Merle, socium domus de Merton. Reproduced and Translated under the supervision of G. J. Symons, F.R.S. (London: Edward Stanford, 1891.)

IN January 1337, barely forty-five years after the death of Roger Bacon, and ten years after the accession of King Edward the Third, William Merle, a Fellow of Merton College, and Rector of Driby, in Lincolnshire, commenced a journal of the current weather as experienced partly at his rectory "in Lyndesay, near the north-east coast," and partly at Oxford. This journal he continued month by month for seven years, or up to three years before his death, the notices of the last four years being considerably amplified over the earlier entries; and the original manuscript, still preserved in the Bodleian Library, has now, thanks to the initiation of Mr.

G. J. Symons, been reproduced in *facsimile* by photography, translated from the monkish Latin of the original text by Miss Parker, and published in a handsome small folio volume, of which one hundred copies have been printed. It is probably, as stated on the title-page, the earliest known weather journal in the world.

The manuscript consists of nine and a half pages of abbreviated Latin, written on vellum in a distinct and easily decipherable text, and is apparently in excellent preservation. It is bound up with a number of other manuscript treatises (one of which is also by Merle) dealing with weather prognostication, astrological lore, and other subjects which, according to the scientific views of the day, were nearly related branches of knowledge. Some of these treatises were collected, and some written by, William Reed, who was Bishop of Chichester from 1369 to 1386, and who bequeathed them to scholars of Merton, "being of his kin." Subsequently, the volume passed into the possession of Sir Kenelm Digby, who, in 1634, presented it, together with other manuscripts, to the Bodleian Library. It is interesting and not uninstructive to note how modest a figure is cut, in this scientific record of the fourteenth century, by the few pages of original observation amid the mass of speculative writings in which they are buried; and how in the nineteenth century they alone retain all their pristine value, and are resuscitated with all the honours of *facsimile* reproduction, while the learned treatises on the conjunctions of the planets, the lunar mansions, and rules for prognosticating the weather, are left undisturbed in the musty dignity in which they have reposed for more than five centuries.

As already remarked, Merle's entries are at first very brief, the notice of each month's weather seldom exceeding two lines of the manuscript. Thus for January 1337 we find:—

> "In January there was warmth with moderate dryness, and in the previous winter [or the previous part of the same winter?] there had not been any considerable cold or humidity, but more dryness and warmth."

Gradually, however, the notes expand, and it is not a little interesting to trace how by degrees the journalist's growing interest in his probably novel undertaking leads him to record more and more in detail the facts that present themselves to his daily observation. Thus from a brief general summary of the characteristic weather of the month, as illustrated in the above quotation, at the end of the year he proceeds to record the character of each week, and towards the end of the third year (1339) he begins to notice the weather of a few special days. From the beginning of 1340 greater amplification is indulged in: the monthly notes often expand to six or eight lines, and in the final year of the record (1343) sometimes to from ten to fourteen lines. In illustration of these more detailed entries, the notice for July 1343 may be quoted:—

> "July.—Considerable heat on the first five days, and it was great on the 3rd and 4th. On the 4th, two or three hours before sunset, heavy thunder began with more vivid lightning than I think I had ever seen, which lasted until midnight, with heavy rain. 5th, light thunder about sunset. On the 6th day and throughout the second week it was gloomy, and there was a slight fog occasionally. 12th, light rain; 14th, gloomy; 15th, and three following days, considerable heat; 19th, rain which penetrated a good deal; 20th, light rain; 22nd, rain; 25th, heavy rain, with heavy thunder in the night, and also in the morning of the following day. All the remainder was rainy, with fog, and rain in small drops, and it was gloomy the whole time. 28th in the night, and 29th in the morning, thunder, with heavy rain. There was lightning with the last two thunderstorms."

For the last four years, indeed, Merle's notes are sufficiently ample to allow of a fair estimate of the weather of those years in comparison with that of the present day, and perhaps some such comparison may be instituted by those who have at command the ample registers of our own time for the same part of Lincolnshire. Seeing how great have been the changes wrought in the character of the surface of the country, by the clearing of forests, drainage, and the extension of agriculture, such a comparison may possibly furnish matter of great interest.

The fourteenth century is sadly memorable for the disastrous famines and pestilences that then desolated England, and above all for the "Black Death," which half depopulated the realm, and was nowhere more fatal than in East Anglia. But this last did not make its first appearance until the end of 1348, about a year after Merle's death, and nearly five years after the conclusion of his journal, which ends abruptly with January 1344; and although a severe famine is recorded in 1335, and another in 1353, it does not appear that any of the years included in his register was especially disastrous. The famine of 1335 is said to have been due to excessive rain, and we may perhaps hazard the surmise that the recent memory of this visitation was the stimulus that induced Merle to record these interesting notes, which good fortune has preserved for us through five and a half centuries.

H. F. B.

OUR BOOK SHELF.

The South Italian Volcanoes. Being the Account of an Excursion to them made by English and other Geologists in 1889, under the auspices of the Geologists' Association of London, with Papers on the Different Localities by Messrs. Johnston-Lavis, Platania, Sambon, Zezi, and Madame Antonia Lavis; including the Bibliography of the Volcanic Districts, and Sixteen Plates. Edited by H. J. Johnston-Lavis, M.D., F.G.S., &c. Pp. 342. (Naples: F. Furchheim, 1891.)

IN this useful volume, Dr. Johnston-Lavis has issued reprints of his report on the Italian excursion made by the members of the Geologists' Association under his direction, and of his abridged sketch of the geology of Vesuvius and Monte Somma, already noticed in this journal. These reprints are accompanied by several interesting original papers—namely, one on the thermo-mineral and gas springs of Sujo, near Roccamonfina, by Dr. Johnston-Lavis himself; one on the geology of Acireale, by Signor G. Platania; another entitled "Notes on the Eolian Islands and on Pumice-stone," by Dr. L. Sambon; and lastly a chapter on "The Travertine and Acque Albule in the neighbourhood of Tivoli," by Signor Pietro Zezi. These various memoirs occupy 88 pages of the volume, the remainder being devoted to a very useful bibliography of Italian vulcanology, compiled by Dr. Johnston-Lavis and Madame Antonia F. Lavis.

Not the least valuable portion of the work is the series of beautiful photographs taken by Dr. Johnston-Lavis from well-selected points of view, and admirably reproduced as small quarto plates. These plates are striking illustrations of what can be accomplished by instantaneous photography as an aid to vulcanological study. Among them are very instructive views of explosive outbursts from the craters of Stromboli and Vulcano. In the case of the small explosions from the first-mentioned volcano, the ejected fragments are seen in the midst of the steam-clouds; and in the case of the more violent eruptions from Vulcano several phases in the same outburst have been caught at intervals of a few seconds. Those who already know this very interesting district will be glad to have their recollections revived by these admirable plates; and those who have never had the pleasure of visiting the South Italian volcanoes may obtain from these remarkable photographs a much better idea of the localities than any descriptions or drawings can possibly give.

Buried Cities and Bible Countries. By George St. Clair, F.G.S. (London: Kegan Paul, Trench, Trübner, and Co., 1891.)

Everyone knows that recent archæological research has brought to light a vast number of facts which are directly or indirectly connected with ancient Hebrew history. The object of the author of the present work is to set forth the more important of these facts, and to explain their significance. He deals with the results of exploration in Egypt, Palestine, and Mesopotamia; and he has a chapter on Jerusalem, with regard to the topography of which he has been led to conclusions different from those of other writers. The book has been prepared for the benefit of persons "who have no time to follow the course of exploration, and no taste for technical details"; and readers of this class will find in it much that will be to them both new and interesting. The value of the text is increased by good maps, plans, and other illustrations.

Food, Physiology, &c. By William Durham, F.R.S.E. (London and Edinburgh: A. and C. Black, 1891.)

This is the third volume of a series by Mr. Durham, entitled "Science in Plain Language." The author does not pretend to say anything new, but he has brought together, and arranged clearly, a mass of facts which will no doubt be of interest, and may be of practical service, to many readers who have neither time nor inclination for the study of more elaborate treatises. He begins with the consideration of solid and liquid foods, then gives some account of the constituents of food, and finally sketches the structure and functions of the bodily organs.

Blackie's Science Readers. (London: Blackie and Son, 1891.)

The aim of this series is to arouse the interest of children in the common objects of the natural world, and to give them some insight into the processes by which articles of ordinary use are produced. The idea is excellent, and has been very successfully worked out. The series consists of five little volumes, the first two of which present some "lessons on common objects." From the third volume the reader will learn something about the simple principles of classification; about substances used in arts and manufactures; about phenomena of earth and atmosphere; and about matter in three states—solids, liquids, and gases. The fourth and fifth volumes—by the Rev. Theodore Wood—deal with animal and plant life. The facts set forth have been carefully selected, and they are presented in a bright, easy, natural style which cannot fail to make them at once intelligible and attractive. Good teachers will find the series of real service in helping them to foster in the minds of their pupils a love of accurate observation and independent reasoning.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Comparative Palatability.

With the view of supplementing the experiments carried out last year by Mr. F. Finn and myself (Nature, vol. xlii. pp. 571, 572), I have been feeding, during August and September, specimens of the common frog and toad.

Among Hymenoptera, *Bombi* are readily taken by frogs. I have records of *B. lapidarius* (drones and workers), *terrestris* (queens and workers), and *muscorum* (drones and workers). On one occasion only a freely-feeding frog refused to attack for the second time a large queen of *terrestris*, which had stung its mouth. Many of the insects were, however, thus taken at the second attempt. The common wasp was eaten eagerly by frogs and toads. I was again unfortunate in not taking any *Chrysididæ*. *Sirex gigas* was attacked both by a frog, for which it seemed too large, and by a toad, under whose lip it appeared to insert its ovipositor. Neither animal ventured to seize it again—certainly for an hour or so. I was then obliged to abandon the observation. I could get no large ichneumons.

Of Lepidoptera, *Vanessa urticæ* was taken by frogs and toads, and *V. io* by a frog. Three or four specimens of *Pieris rapæ* and *napi* would be taken in succession by a frog, which also ate *P. brassicæ*. The insects' flutterings did not seem to matter: more than once they were taken on the wing. A toad once took *P. rapæ*. I was surprised to see a frog seize a dead specimen of this butterfly, which had been lying for several hours in the inclosure. It was partially swallowed, but rejected after some seconds—having unfortunately been taken together with some cedar needles. *Plusia gamma* was eaten eagerly by both frogs and toads. Hairy caterpillars (*e.g.* of *Orgyia antiqua* and *Spilosoma* sp.) were taken by a frog. Smooth green larvæ were eaten greedily.

Of Diptera, *Eristalis tenax* was eagerly seized by frogs and toads. A red-tailed, long-winged fly was eaten by a frog.

Blatta orientalis was taken without hesitation; as were, of course, earthworms.

Of three frogs under observation, only one was of much working value. This specimen (a male) became in a fortnight so tame as to attempt to take the handle of the butterfly-net with which I placed the insects, &c., in the inclosure. This fact recalls Mr. E. B. Poulton's observation, that his tree-frogs seized the end of the forceps with which food was given them.

It is, perhaps, worthy of notice that the larvæ of the blow-fly, though eaten eagerly by toads, are frequently passed whole from the body; and would, therefore, seem to be with difficulty digested.

Want of time has prevented my experimenting, as I had wished to do, with *Salamandra maculosa*. Mr. F. Finn offered a specimen to ducks, which will eat the small newt, and found that though more than one bird observed it, and one even ran towards it, it was not touched. The observation extended over more than an hour.

Alum Solution.

Dans le no. 1141 de votre excellente Revue, M. Napier Draper demande pour quelle raison la solution d'alun a été universellement adoptée pour l'absorption des radiations de grande longueur d'onde. Ce n'est point pour répondre à cette question que je vous écris, car, pas plus que votre correspondant, je ne connais d'expériences directes suffisamment exactes desquelles il résulterait que la solution d'alun absorbe plus que l'eau pure. Je hasarderai, cependant, une explication: l'eau est un des liquides transparents les plus absorbants; l'alun occupe un rang analogue parmi les solides; en dehors de toute vérification, si l'absorption sélective de chacun de ces corps s'exerce sur une partie différente du spectre, on peut supposer que leur mélange exerce une absorption plus complète que chacun des corps pris isolément.

A cette occasion, je prendrai la liberté de relever une erreur que l'on a fréquemment commise dans ces derniers temps au sujet de l'absorption des radiations infra-rouges par l'eau. On a coutume de définir le rendement d'un foyer de lumière par le rapport de l'énergie située dans la partie visible du spectre à l'énergie totale rayonnée par le foyer. Sans insister sur ce que cette définition a de défectueux (je traiterai prochainement cette question dans la *Revue générale des Sciences*), je rappellerai qu'on mesure d'ordinaire le rendement en recevant successivement sur un radiomètre quelconque (pile de Melloni, bolomètre, radiomicromètre de Boys) la radiation totale du foyer, et la radiation qui a traversé une certaine épaisseur d'eau; on admet que les radiations obscures ont été retenues, et on fait le quotient de ces deux quantités. Aucun physicien, je suppose, ne croit que l'absorption par l'eau commence à l'endroit précis où cesse la vision, et devient immédiatement totale, mais on pense en général que le résultat ainsi obtenu est assez approché.

Or nous pouvons déterminer directement le rendement photogénique d'une source en mesurant la superficie des courbes d'énergie rayonnante visible et invisible. En partant des nombres de M. Langley, on trouve ainsi, pour le rendement d'une lampe à gaz une valeur comprise entre 1 et 2 pour cent. D'autre part, les recherches de M. Knut Ångström ont montré que l'absorption par l'eau est presque nulle pour $\lambda = 1\mu$, et n'est totale qu'à partir de $\lambda = 2\mu$ environ. Une couche épaisse d'eau laisse passer près de 10 pour cent de l'énergie rayonnante invisible. La méthode ordinaire donnerait donc, pour le rendement d'une lampe à gaz, 11 à 12 pour cent, c'est à dire une quantité six fois trop forte.

Je ne quitterai pas ce sujet sans faire remarquer le singulier usage en vertu duquel la puissance de la radiation solaire est rapportée à la *minute*, tandis que toutes les puissances possibles—cheval, *horse-power*, watt, ainsi que toutes les radiations—sont exprimées par rapport à la seconde. Il serait temps de faire disparaître cette anomalie.

Weather Cycles.

With reference to this most interesting question, may I be allowed to call attention to the following figures? Having had to consult Dr. Rutty's "Natural History of Dublin," 1772, vol. ii., I casually found on p. 353 of that volume, in his remarkable detailed registry of the weather in Dublin for a long series of years, the following remark: "It has been remarked that the following years were memorable for great frosts in England, viz. 1638, 1661, 1684, 1708, 1716, 1739." Now the intervals between these dates are 23, 23, 24, 8, 23. He further remarks, on p. 368:—"It is to be observed that whereas since the great frost of 1739, until the latter end of the present summer, 1744, we had generally an unusual prevalence of dry weather, in autumn our usual wet weather returned." It may be remarked that the interval of 23 years is about double the sun-spot period, and furthermore that the years mentioned by Rutty correspond roughly with years of sun-spot minima or maxima as given in Wolf's Catalogue, mentioned by Guillemin in his work "Le Ciel" (1877), p. 104. This correspondence would appear as follows:—

Sun-spot Year.	Interval.	Great colds.	Interval.
1639·5 min.		1638	
	20·5		23
1660 min.		1661	
	25		23
1685 min.		1684	
	20·5		24
1705·5 min.		1708	
	12·5		8
1718 min.		1716	
	20·7		23
1738·7 min.		1739	
	16·8		15
1755·5 max.	22·8	1754	23
	6·0		8
1761·5 max.		1762

Occurrence of the Ringed Snake in the Sea.

The readiness with which the British snake (*Tropidonotus natrix*) will enter fresh water is well known. Its occurrence in the sea seems anomalous, and therefore I venture to submit the following details.

The specimen in question was seen on September 7, from a small boat on the east coast of the Isle of Wight, while about a thousand yards distant from the shore, and about midway between Shanklin and Luccombe Chines. When first seen it was swimming straight out to sea—viz. in an easterly direction. The sea was calm and a strong current was flowing from the south, so that the creature was swimming across the current. At first it took no notice of the boat, but as the boat was rowed towards it, it changed its course and swam directly away from the boat. It was soon captured, and found to be uninjured and in good condition. Upon dissection it proved to be a male; the entire alimentary canal was absolutely empty. The internal organs were free from disease or other abnormality. It measured 33 inches in length. It is most probable that this snake entered the sea about a mile from where it was obtained, as the beach is bounded by almost perpendicular cliffs, some 300 feet high, at that place.

J. Cowper.

A Rare Phenomenon.

Mr. Wilson's letter in your issue of September 24 (p. 494), recalls what I myself saw on the same evening. On Friday, the 11th, I was returning with a friend to town after a day's ramble in Epping Forest. We caught the 8.36 p.m. train at Epping, which is due at Woodford at 8.59, and was, I think, only a few minutes late. Just as the train was nearing Woodford Station, my friend and myself simultaneously noticed a luminous band, such as that observed by Mr. Wilson, and extending from the horizon almost to the zenith. Our first unreflecting thought was to refer it to the revolving light at the Naval Exhibition, only it did not revolve, and the direction was quite wrong. The fact that both of us thought of this is indicative of the appearance which the luminous beam bore. The night was clear and starlit, and I observed that the point in the horizon from which the beam rose was almost under the Great Bear, but a little to the left as I faced it. We saw it only for a minute or two before it was hidden from us by the shed of Woodford Station, in which station we stayed for what seemed a long while. When we got into the open country again, the phenomenon had disappeared. I may add, that my own eye being unfortunately defective for red, I asked my companion if he noticed any red tinge in the light, and he answered that it seemed quite white.

Burlington House. Herbert Rix.

The narrow luminous band described in Nature, September 24 (p. 494) was seen here on Friday, the 11th inst., between 8.30 and 9 p.m., at the same time at which it was seen by Mr. Wilson in the county Westmeath, but about twenty-two hours later than it was seen by Prof. Copeland in Aberdeenshire. It passed close south of Cassiopeia, and nearly through the zenith. Half an hour later it had drifted 8° or 10° southward, and had become very faint.

There can be little doubt that the very rapidly moving "comet" seen by Mr. Eddie at Grahamstown, South Africa, on October 27, 1890, was a phenomenon of this kind.

J. L. E. Dreyer.

The Observatory, Armagh, September 28.

The Heights of Auroras.

The rare part of the phenomena described by your correspondents is the extreme narrowness of the auroral arches seen on the 10th in the north of Scotland, and on the 11th at Ryde. I take all the other descriptions on the 11th to refer to one arch—a different one from that seen at Ryde; and it was a much wider one, and therefore less unusual, its width having been about 5° as seen here. Your correspondents do not give its width, except that, as seen from Nottingham, it was evidently very broad, and is not stated to have been an arch at all, though I should suppose it was one. The observation at Nottingham Forest, compared with those further north, gives a good opportunity for ascertaining the height of the top of the aurora; but, as Mr. A. Marshall has not given the altitude of the base of the aurora as seen from Nottingham, there are no materials for calculating the height of that. I made several observations of the position of the central line of the arch. I might specify that at 9.25 it was at R.A. 20h. 42m., Decl. + 33½°, and R.A. 0h. 43m., Decl. + 33°, and it moved very slowly.

Is it not time some systematic effort was made to calculate the heights of auroras? A good many observations have been made on this point, showing great variation in height; and yet, beyond the conclusion that it seems probable they may be seen at lower elevations nearer the magnetic pole than elsewhere, we know nothing as to whether they vary in height with the place, the time, or the nature of the auroras. Now is the time, seeing that auroras appear to be becoming more numerous than they have been for many years past. T. W. Backhouse.

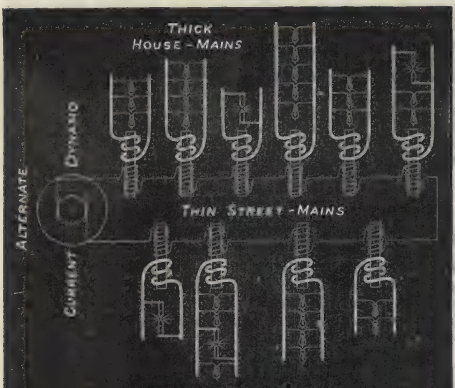
West Hendon House, Sunderland, October 5.

SOME NOTES ON THE FRANKFORT INTERNATIONAL ELECTRICAL EXHIBITION.[1]

III.

From One Hundred to Twenty Thousand Volts.

The incandescent lamp having, by 1885, reached a fair degree of perfection, it appeared that the one need still remaining, in connection with the distribution of the electric light over a large area, would be supplied by the use of transformers. For a transformer with many convolutions of fine insulated wire on one coil, and a few convolutions of thick insulated wire on the other, would transform a large pressure and small current into a small pressure and large current; hence, if such a transformer were placed in each house, it would be possible to light up even a scattered district by a comparatively fine wire from a central station, whereas previously it had seemed that it would be necessary to use copper conductors many square inches in cross-section to light many houses even when at no great distance from one another.



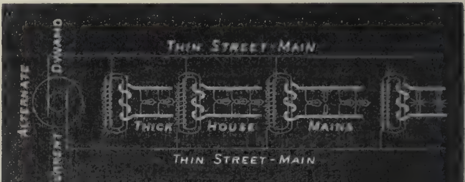
Transformers in Series
Gaulard and Gibbs' Original Arrangement.
Fig. 2

Hence, in the autumn of 1885 we find Messrs. Gaulard and Gibbs making preparations at the Grosvenor Gallery, Bond Street, for establishing there the pioneer central station for London.

But the method they adopted was that of placing the transformers in series, as seen in Fig. 2, and this system has the great disadvantage that the brightness of the electric lamps in a house cannot be kept automatically constant when other lamps in the same house are turned on or off. There are, of course, two conditions to be fulfilled in electric lighting: one, that turning on or off lamps in one house shall not affect the brightness of the lamps in any other house; the other, that turning on or off lamps in one room shall not affect the brightness of the lamps in any other room of the same house. With transformers in series, the first condition is satisfied by keeping the alternating current which passes through the fine wire or *primary coil* of the transformer perfectly constant; but this does not render the potential difference between the wires from the *secondary circuit*, or house mains, independent of the current in this secondary circuit—that is, independent of the number of lamps turned on in the house. Consequently, the series arrangement of transformers adopted by Messrs. Gaulard and Gibbs, while rendering the lamps in one house independent of those in another, did not attain the same result for lamps in different rooms of the same house.

Complaints, therefore, became general. Various unsuccessful devices were tried to remedy this evil, when an application was received from Mr. Sebastian Ziani de Ferranti to be allowed to try a transformer which he had designed. The application was accepted, for Mr. Ferranti, although quite young, was already known as having constructed an ingenious alternate-current dynamo, and in February 1886 the charge of the Grosvenor Gallery central station passed over into Mr. Ferranti's hands.

The new engineer recommended that the system of placing the transformers in series should be totally discarded, and that a parallel arrangement should be adopted in its place, as in Fig. 3, because a well-made transformer had this important property—that if the potential difference at the terminals of the primary coil were kept constant, the potential difference between the terminals of the secondary coil would also remain nearly constant whatever were the current passing through this circuit; so that if the pressure between the street mains were always kept the same, the brightness of the lamps would hardly be affected either by turning on or off lamps in the same or in any other house.



Transformers in Parallel
Arrangement Now Adopted
Fig 3.

Placing the transformers in parallel, however, would necessitate working at a low pressure, said the press, and would rob the transformer system of all its value, for "it is surely not proposed for one moment to work a parallel system where the primary has a difference of potential of 2000 volts." However, that is exactly what Mr. Ferranti not only proposed to do, but what he actually carried out on a large scale, so that his mains by 1888 stretched from Regent's Park to the Thames, and from Chancery Lane to Hyde Park, supplying current to some 20,000 glow-lamps. The Board of Trade had made regulations, about 200 volts being the maximum pressure permitted in a house; Parliament had passed the Electric Lighting Act of 1882, containing clauses rendering the development of the electric lighting industry well nigh commercially impossible; but Mr. Ferranti overcame all these legalities by bridging his mains from house-top to house-top, instead of putting them under the streets and himself under the control of the authorities.

---

[1] Continued from p. 524.

But every corner at the Bond Street central station had soon to be utilized; a dynamo weighing tons had on one occasion to be lifted into position over a steam-engine necessarily kept always running to maintain a constant supply of current to the houses. New customers were added daily to the list, more and more current had to be generated nightly, in the face of engineering difficulties, and in the teeth of injunctions against smoke, injunctions against dust, and injunctions against noise.

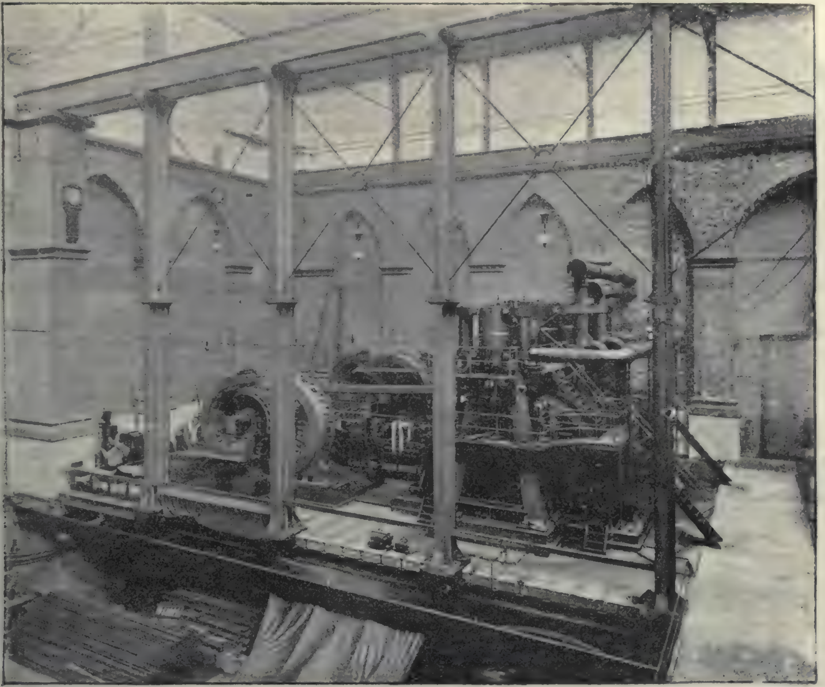


Fig. 4.—Two 1250 horse-power dynamos (opened for inspection) at Deptford.

A fresh start became imperative, so it was decided to build at Deptford, 6 miles away from Bond Street, a vast generating station, which should be the largest in the world, and to use the Grosvenor Gallery, and probably fresh sites to be obtained in town, merely as transforming stations. In the mains between Deptford and London it was decided to employ 10,000 volts, to be reduced to 2400 in London, and the power then distributed by the existing overhead mains, and again reduced to 100 volts on entering the houses, as before.

The scheme was a far-reaching one; permission was asked from the Board of Trade by the London Electric Supply Corporation, the outcome of the original Grosvenor Gallery Syndicate, to run wires along 27 railways and through 30 parishes; two dynamos, each to furnish 1250 horse-power at 10,000 volts, were built with special engines to drive them, as seen in Fig. 4, and a cable laid to London. But on starting the dynamos, when they were completed, it was found that the insulation of the cable would not stand 10,000 nor even 5000 volts; and for a time power was supplied direct from Deptford to the houses in London, one transformation at the houses themselves being alone effected.

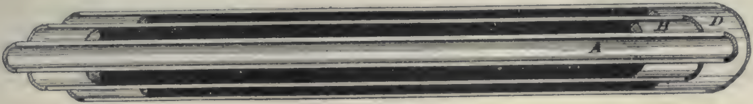

Fig. 5.—Longitudinal section of the Ferranti main. A, inner copper tube; B, outer copper tube; D, iron protecting tube; waxed paper insulation shaded black.

Then Mr. Ferranti carried out his original intention of constructing the main of two concentric copper tubes, to serve respectively as the going and return conductor. The inner copper tube, 20 feet long, seen in section, A, W.E. Ayrton, "Some Notes on the Frankfort Int. Electrical Exh." 44

Fig. 5, has brown paper soaked in ozokerit rolled round it to a thickness of about five-eighths of an inch. Outside this is slipped a larger copper tube, B, Fig. 5, and the whole is drawn through a taper die under great pressure, which has the effect of forcibly compressing the paper and consolidating the mass. Next, more brown paper soaked in melted ozokerit is rolled on, to a thickness of one-eighth of an inch, and the whole slipped loosely into an iron tube, D, Fig. 5, which protects the cable subsequently from mechanical injury. To fill up any air spaces that may have been left between the iron and the outer copper tubes, the 20-feet section is placed over a fire, and melted wax pumped in between the two through a tube inserted in a hole drilled in the middle of the iron tube.

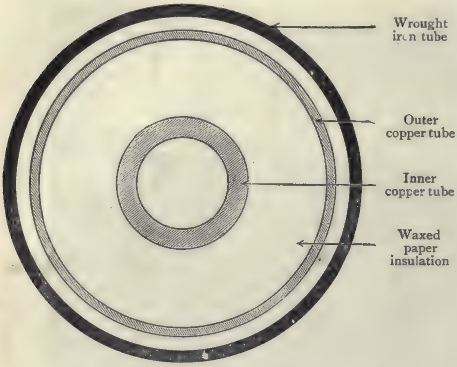

FIG. 6.—Cross-section of the Ferranti main; full size.

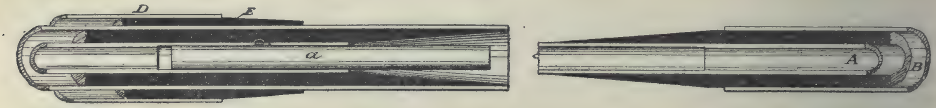

FIG. 7.—Ends of two pieces of main, tapered ready for jointing. *a*, copper rod to make electric connection between inner copper tubes; E, waxed paper coned like a pencil.

Fig. 6 shows a cross-section of the finished main full size, and as the sectional area of the metal in each of the copper tubes is about a quarter of a square inch, the main can transmit about 2000 horse-power at 10,000 volts.

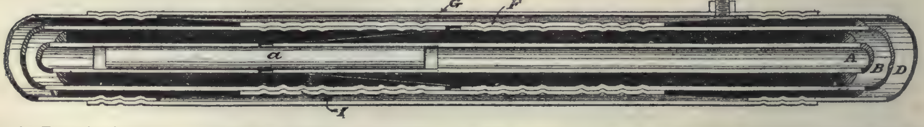

FIG. 8.—Ferranti main, jointed. F, copper sleeve slipped over two ends of outer copper tubes, and then corrugated with special tool; G, iron sleeve slipped over two ends of iron tubes, and corrugated with special tool; H, screw-hole to run in melted wax, I.

The main being constructed in lengths of only 20 feet, some 1500 joints have had to be made in 6 miles of main, or 6500 joints altogether in the five mains which have been laid from London to Deptford. These joints have been made without solder, in the way shown in Figs. 7 and 8, pressure alone between the copper tubes having been relied on to maintain good contact.

The object of using concentric tubes is twofold—first, as the outer copper tube is kept practically at the potential of the earth, it is impossible to get a severe shock unless the inner tube is touched, and this, of course, can only be done by first cutting through the outer; second, the effective increase of the resistance and of the self-induction which occurs with rapidly alternating currents in consequence of the mutual action of the currents in different parts of the conductor on one another is much less for a given cross-section of copper with concentric tubes than with two insulated rods placed side by side. For example, Sir William Thomson has calculated that if copper be employed in the form of a solid rod, 1·2 inch in diameter, the resistance for an alternating current of a frequency of 80 per second will be 31 per cent. greater than for a steady current.

It is very questionable, however, whether these advantages of using concentric tubes are not more than compensated for by the large electrostatic capacity that such a cable possesses. For, as is now fully recognized, the combination of capacity and self-induction can by a species of resonance cause the difference of potential in the circuit to be far greater than the E.M.F. of the dynamo itself, and in certain cases, very dangerously greater.

As soon as the Deptford main was constructed to stand 10,000 volts, it was found that one of the dynamos seen in Fig. 4 broke down at this pressure, and therefore for many months the current was sent from Deptford at only 5000 volts; next, the transformer room at the Grosvenor Gallery was burnt down through carelessness, some £8000 worth of transformers destroyed, and a portion of London left in darkness for two or three weeks. New transformers were hastily, too hastily, constructed, and the current was turned on again at the commencement of last December; but after a few days the transformers were, one after another, short-circuited by the electric current sparking from the primary coil to the iron core of the transformers, and all the houses on the London Electric Supply Corporation's system again left in darkness during the nearly perpetual night of a densely foggy winter. The Metropolitan Electric Supply Company—which also distributes an alternating current by means of transformers, but from several central stations in the heart of London itself, and therefore requiring to use only 1000 volts and a single transformation—came to the rescue in certain districts, but in others the householders had to be left to their fate, as it would have been far too expensive to run special mains from the Metropolitan Company's stations merely as a temporary expedient.

Finally, in March of this year, current was again turned on from Deptford, at the pressure originally proposed, viz. 10,000 volts. It was not, however, supplied from the dynamos illustrated in Fig. 4; but, instead, Messrs. Deprez and Carpentier's plan of transforming up and transforming down again, illustrated in Fig. 1, p. 522, was employed. For, by this time, two dynamos, formerly at the Grosvenor Gallery, each of 600 horse-power, had been taken to Deptford and erected there, as seen in Fig. 9; new steam-engines, more powerful than those formerly employed at the Grosvenor Gallery, having been constructed to drive them.

These dynamos generate the current at 2400 volts, then, by means of transformers at Deptford, this is raised to 10,000 volts. On the power arriving in London, the pressure is transformed down again to 2400 volts, and at the houses there is a further transformation of this 2400 volts to 100 volts. There are, therefore, no less than three transformations of pressure between the dynamo terminals at Deptford and the lamps in the houses in London.

Regarded as a gigantic experiment in electrical engineering, the Deptford scheme has achieved a gallant victory, for, with a buoyancy that no disaster could crush, and with the determination of a Napoleon to conquer every mechanical and electrical obstacle in the way, Mr. Ferranti has step by step succeeded in distributing current to quite distant parts of London at a pressure which in 1885 was regarded as quite impracticable, and for the last seven months he has been sending the power to London at a pressure which, even at the end of last year, was deemed simply visionary.

But as a commercial undertaking the Deptford transmission is a dreary failure, since what is the advantage of transmitting the current 6 miles that is in any way commensurate with the capital already expended? When power can be obtained very cheaply, from a rapid river for example, it may be highly remunerative to transport it in some such way as is now being done between Lauffen and Frankfort. But can power be obtained so much more cheaply at Deptford than in London to make it worth while transmitting it over 6 miles? Land undoubtedly costs much less down the river than in the heart of London, coal can be very easily brought to a generating station on the banks of the Thames, and the water might perhaps be employed to work condensing steam-engines; but such economies can only compensate for a fraction of the yearly interest on the capital expended on the Deptford scheme. Indeed, even if the station at Deptford had been built with rigid economy, and only large enough for the present demand, it is questionable whether the loss of power in three transformations of the pressure would not eat up much of the saving that could be effected by having the generating station quite out of London.

As it is, however, the London Electric Supply Company have been so engrossed with the electric lighting of London in the *future*, that they have practically ignored the present wants of the householder; the vast building at Deptford has been constructed to carry a second story

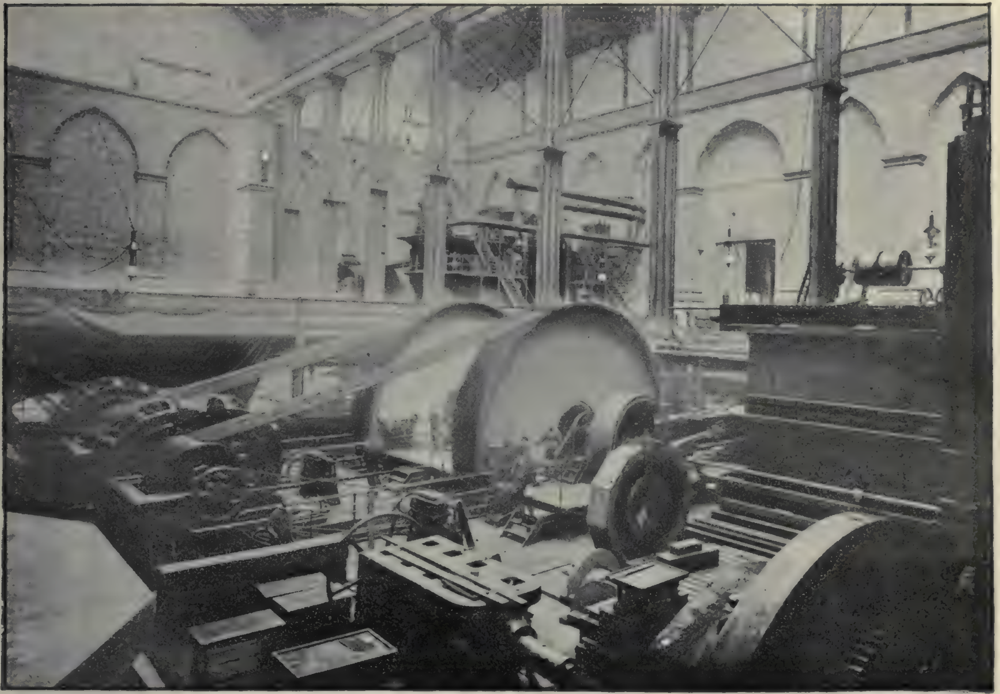

FIG. 9.—Two of the Grosvenor Gallery dynamos re erected at Deptford and driven by new steam-engines. Two 1250 horse-power dynamos at the back.

of boilers and engines, when it is very doubtful if even the present story can be wholly utilized for a long time to come; rows of boilers and furnaces were erected some two or three years ago to supply steam to drive dynamos which are not yet made; tens of thousands of pounds have been expended on machinery to be employed in constructing two ten-thousand horse-power dynamos, and the armature of one of them, 43 feet in diameter, has had to be left abandoned only half finished, because there is neither money nor present need for such a dynamo at Deptford.

And while all these provisions for the future electric lighting of London on a vast scale were slowly proceeding, the present customers were left sometimes for hours, sometimes for days, and occasionally even for weeks in darkness: what wonder is it, then, that all over London there have have been growing up central stations supplying a direct current at low pressure, and that many of the householders who formerly received current from the overhead wires of the London Electric Supply Corporation have had their houses connected instead with the low-pressure underground mains of other companies?

To the world at large, however, the Deptford undertaking has been of immense value, for it has shown the possibility of practically using the very high potential differences absolutely necessary for economically transmitting power over such distances as that between Lauffen and Frankfort. Hence, maintaining 20,000 volts between *bare* wires running for 109 miles along the side of the Neckar railway, at a height of only 16 feet from the ground, sounds much less startling now than did Mr. Ferranti's proposal made and acted on five years ago to bring only one-tenth of this pressure, by means of india-rubber covered conductors, into locked transformer rooms built of brick in the basement of the houses supplied with current from the Grosvenor Gallery.

In fact, the results that have been attained through Mr. Ferranti's undaunted courage, and the well-filled purses of his friends, have led people to look on a pressure of 20,000 volts as they regard a velocity of 70 miles an hour, so that to day, in order to prevent boys climbing up any one of the 3000 ordinary telegraph poles which carry the wires from Lauffen to Frankfort, it is thought sufficient to merely paint a skull and cross-bones on every post as an indication of the deadly fate that awaits the climber.[1]

(*To be continued.*)

ON VAN DER WAALS'S TREATMENT OF LAPLACE'S PRESSURE IN THE VIRIAL EQUATION: IN ANSWER TO LORD RAYLEIGH.

MY DEAR LORD RAYLEIGH,—As you are aware, I did not see your letter of September 7 (NATURE, 24/9/91) till a fortnight after its date; and my reply has been further delayed for a week in consequence of the closing of Edinburgh University Library at this season. Even now I can refer only to the German version of Van der Waals's pamphlet.

Partly on account of its unfamiliar language, but more especially on account of a very definite unfavourable opinion expressed by Clerk-Maxwell (NATURE, 15/10/74) I did not attempt to read the pamphlet when it appeared; and it was not till 1888 that, in consequence of some hints from Dr. H. Du Bois, I hastily perused it in its German form.

The passage which you quote from my paper (where, by the way, the printers have unfortunately put *resistance* for *resilience*) is certainly not a very accurate description of Van der Waals's method, but it represents faithfully the difficulties which I felt on first reading the pamphlet. I said that Van der Waals's "justification of the introduction of the term a/v^2 into an account already closed, as it were, escapes me." And I am not surprised that it did so. For the statement of Clerk-Maxwell had prepared me to look for error; and when, at the end of Chap. VI., I met with the formula

$$p(v-b) = \mathrm{R}(1+at),$$

which, a couple of pages later (nothing but general reasoning intervening), somehow developed itself into

$$\left(p+\frac{a}{v^2}\right)(v-b) = \mathrm{R}(1+at),$$

I naturally concluded that this was the matter adverted to. I spoke of the first of these equations as a "closed account," because of the process by which b had been introduced. To this point I must presently recur.

I had not examined with any particular care the opening chapters, to which your letter chiefly refers; probably having supposed them to contain nothing beyond a statement and proof of the Virial Theorem (with which I was already familiar) along with a reproduction of a good deal of Laplace's work.

Of course your account of this earlier part of the pamphlet (which I have now, for the first time, read with care) is correct. But I do not see that any part of my statements (with perhaps the single exception of the now italicized word in the phrase "the *whole* procedure is erroneous") is invalidated by it. No doubt, the sudden appearance of a/v^2 in the formula above quoted is, to some extent at least, accounted for; but is the term correctly introduced?

The formula you give would lead, on Van der Waals's principles as to the interpretation of $\frac{1}{3}\Sigma(mV^2)$, to

$$v(p+\mathrm{K}) = \mathrm{R}(1+at),$$

or

$$v\left(p+\frac{a}{v^2}\right) = \mathrm{R}(1+at).$$

But how can the factor $(v-b)/v$, which Van der Waals introduces on the left in consequence of the finite diameters of the particles, be justifiably applied to the term in K as well as to that in p? Yet to apply it so is essential to Van der Waals's theory; for without it the resulting equation will not give a cubic in v, and cannot therefore be applied to the isothermals for which it is required. And, in any case, it could scarcely be said that the K term, after being manipulated in this manner, is, in any strict sense, "extracted from the term $\Sigma(\mathrm{R}r)$."

A very strange thing appears, in this connection, in the German version. A result, due it seems to Lorentz (which, in ignorance of his work, I had reproduced and published in the first part of my paper), leads directly to the equation

$$pv = \mathrm{R}(1+at)\left(1+\frac{b}{v}\right);$$

which is then put in the confessedly approximate form

$$p(v-b) = \mathrm{R}(1+at).$$

Of this it is remarked:—"was genau mit dem obigen Resultate [that obtained by the use of the factor $(v-b)/v$] übereinstimmt." It is obvious that, when we have to divide both sides by $v-b$, we ought to restore the proper factor on the right; and thus that the equation ought to take the final form

$$p+\frac{a}{v^2} = \mathrm{R}(1+at)\,\frac{v+b}{v^2},$$

instead of the more convenient form

$$p+\frac{a}{v^2} = \frac{\mathrm{R}(1+at)}{v-b},$$

in which Van der Waals employs it. But then it would not give the required cubic in v!

I think that the mere fact of Van der Waals's saying (in a passage which is evidently applicable to his own processes, though it is applied only to that of Lorentz) "die ganze Rechnung doch nur bis auf Grössen der ersten Ordnung (wie b/v) genau ist" throws very grave doubt on the whole investigation. For in the most interesting part of the critical isothermal of CO_2 the fraction b/v cannot be looked upon as a small quantity of the first order. In fact, without raising the question, either of Van der Waals's mode of interpreting the term $\frac{1}{2}\Sigma(mV^2)$ or of the paucity of constants in his equation, the above consideration would of itself render the results untrustworthy. Van der Waals has most opportunely and effectively called attention to an exceedingly promising mode of attacking a very difficult problem, and his methods are both ingenious and suggestive; but I do not think that his results can be regarded, even from the most favourable point of view, as more than "*Guesses at Truth.*"

---

[1] We have to thank the *Electrician* and the *Electrical Review* for some of the illustrations used in this article.

For, if we take the experimental test, there can be no doubt that (as I have stated in § 65 of my paper) "Van der Waals's curves cannot be made to coincide with those of Andrews." And I think I have given reasons for believing that "the term of Van der Waals's equation, which he took to represent Laplace's K, is not the statical pressure due to molecular forces but (approximately) its excess over the repulsion due to the speed of the particles." Of course I mean by this that, when Van der Waals, comparing his equation with experiment, assigns a numerical value to his term a/v^2, he is not justified in regarding it as the value of Laplace's K; though that quantity was, he tells us, the main object of his inquiry.

Believe me yours very truly,

P. G. TAIT.

St. Andrews, September 28.

THE EXISTING SCHOOLS OF SCIENCE AND ART.

AT a meeting of influential science and art teachers held at the Charterhouse School of Science and Art, Goswell Road, on the 3rd instant, the position of existing schools, with regard to the fierce opposition offered by highly endowed Polytechnics, was calmly and broadly discussed.

For many years, under the system not only recognized but encouraged by the Science and Art Department, schools have been established in London and the provinces. The aid afforded by the Department has mainly been (1) to contribute largely to the building fund of schools intended for the exclusive teaching of science and art subjects, and (2) to remunerate by Government grant the services of the teachers engaged. The regulations of the Department provide that such aid is given to any centre where the need of it is apparent. It is, however, perfectly well known that the teacher, in the majority of cases, was the person upon whom the duty fell to organize the classes and set the ball rolling, and it would be difficult to mention any school or institute in which the motive spirit was not a teacher.

By recent Acts of Parliament a great impetus has been given to that side of science and art instruction known as technical education. Funds which in past times could only have been raised by persistent begging are now forthcoming almost as a matter of routine. In the provinces there is every sign that the authorities having the administration of the grant of public moneys intend to recognize existing schools. In London it is not so Schemes for the erection of new buildings are pushed forward without due regard to those institutions already doing a good work. At the meeting of teachers already referred to several instances were cited. The People's Palace, erected almost in the very shadow of the Bow and Bromley Institute, has, by reason of its endowment, greatly hampered and harassed the older institution. The West London School of Art succumbed two years ago to the attack of the Regent Street Polytechnic; and now the St. Martin's School of Art, one of the best known centres of instruction in the metropolis, has closed its doors. Without endowment it could not compete with its more favoured rivals. The closing of this school is the more to be regretted because of the high tone of the work carried on within its walls.

Unfortunately, it cannot be denied that many so-called schools of science and art are simply carried on as "grant-earning" establishments, and the country would lose little or nothing if they were closed at once. But there are others affording excellent science and art instruction; and though these may not be affected by the present Polytechnics, it is evident that the schemes yet in embryo for the erection of other buildings will, if not properly checked, raise an undignified competition with the older schools. It is therefore a matter of great public importance that the established institutions should not be overlooked by the London County Council. If new buildings are deemed to be necessary, the old school of science and art should be treated as the nucleus of the enlarged scheme.

Two points of error seem to be apparent in the plan of campaign of the supporters of Polytechnics—(1) that educational work must be associated with recreation; and (2) that technical education has a very limited area, and that science and art education in its fullest sense is unnecessary.

"Schools of art," said a gentleman to me recently, "are dead." Surely nothing could be more absurd. As I understand technical education, it is the application of general principles to a specific purpose. Schools of science and art—*i.e.* schools for the study of science as science, and art as art—should be encouraged as much as before. This can be done without interfering with the specific application of such study to a particular purpose.

With regard to the question of recreation, I think it would be found that, although those institutes which make much of athleticism and such matters attract the largest proportion of students, the attendance *pro ratâ* in the classrooms, and the results obtained there, would not favourably compare with an institute carrying out a purely educational programme. At the meeting referred to, one teacher stated that, although at a Polytechnic with which he had been connected only seven students entered the class, scores of young men could be found in the billiard-room and gymnasium. At the Science and Art Institute, Wolverton, one of the best and most practical schools in the country, it was decided to close the billiard-room in consequence of the serious effect it had upon the attendance of students at the classes. I am personally acquainted with the science and art work carried on at the Regent Street Polytechnic. Excellent as it is, it would be still better if it could be relieved of the recreative element.

The London County Council has shelved for a time the appropriation of the funds provided by the Excise Act, 1890, for the promotion of technical education. But the matter must soon come up again. Healthy competition is excellent, but in this matter it is clearly not to the interest of the public that its money should be used for pushing on a new venture as a competitor to, and in antagonism with, an existing institution. The best butcher's shop in London would stand a poor chance if a rival establishment run with money raised by taxation, and not of necessity expected to pay its way, opened its doors on the opposite side of the road; and this is practically the state of affairs. The teachers, moreover, have a perfect right to be heard on this question. Devoting their best years to the training necessary for science and art teaching, it may be urged that they have a moral, if not a legal, claim to be considered.

In concluding, I would point out that the exponents of technical instruction are too keen on "centralization."

Let us have large buildings with costly apparatus and every convenience, but do not entirely crush the small schools. To the working man with limited time and means, weary with his day's toil, a modest school close at hand is of greater service than a huge building six miles away involving railway fare and loss of time. By careful arrangements such smaller schools can be preserved, and largely used as "feeders" for the institutes of magnitude.

The whole matter, therefore, of science and art schools and future Polytechnics should be referred to duly qualified men. There is no reason why existing machinery should not fit in with the new plant to make an harmonious whole.

OLIVER S. DAWSON.

NOTES.

THE autumn meeting of the Iron and Steel Institute was opened at the Royal Arsenal, Woolwich, on Tuesday, the greater part of the day being devoted to an examination of the various departments of the Arsenal. On Wednesday papers were discussed, and to-day visits are to be made to the Naval Exhibition, the Enfield Small Arms Factory, and the Thames Iron Works. We hope to print next week an account of the proceedings.

AN exhibition of cone-bearing trees and shrubs, asters, and sunflowers, and a conference upon them, were opened in the Royal Horticultural Society's Gardens, Chiswick, on Tuesday. Large numbers of conifers were sent from various parts of the country, no fewer than 30 collections coming from Scotland. The first prize was awarded to the Dowager Marchioness of Huntly for her collection of conifers, the second to Lord Wimborne. The largest araucarian cones were sent from Lady Fortescue's, at Dropmore, Maidenhead, where there is an araucaria 68 feet high—the tallest male araucaria in this country. Kew Gardens contributed about 200 different conifers. On Tuesday papers were read on asters and sunflowers. The conference on conifers began on Wednesday, and is being continued to-day.

A COMMISSION of engineers representing the various European Powers is to meet shortly at Cairo to consider the question of a storage reservoir, and to advise the Egyptian Government on the subject. The Commission will be required to select a site to the north of Wady Halfa, or within the present limits of Egypt.

THE organizers of the International Folk Lore Congress are to be congratulated on the success of their undertaking. The attendance was good; many excellent papers were read; and there were animated and suggestive discussions on most of the problems which are now of especial interest to students of folk-lore. Mr. Andrew Lang, as President, delivered the opening address, in which he presented a most interesting statement of what he conceives to be the fundamental principles of the science. Admirable addresses were also delivered by Mr. Sidney Hartland, Prof. Rhys, and Sir Frederick Pollock, who presided respectively over the Sections devoted to folk-tales, mythology, and institutions and customs. The members of the Congress dined together at the Criterion Restaurant on Tuesday evening.

STUDENTS of psychology and philosophy will read with regret Prof. Croom Robertson's "valedictory" words in *Mind*, from the editorship of which the state of his health makes it necessary for him to retire. For sixteen years he has done his work as editor with conspicuous ability and success. A second series of the Review will be begun next quarter. It will be under a co-operative direction which promises, Prof. Croom Robertson thinks, "a far more effective covering of the ground of psychology and philosophy than has hitherto been attained."

THE seventh of the series of One Man Photographic Exhibitions is now being held at the Camera Club. It is open to visitors from 10 a.m. to 4 p.m. on presentation of cards, which can be obtained from members or from the Hon. Secretary. The exhibition consists of photographs by Mr. Ralph W. Robinson.

WE learn from the *Botanical Gazette* that Mr. O. F. Cook, Instructor in Biology at the University of Syracuse, U.S.A., intends starting about November 1 in charge of an expedition to Liberia and other parts of Africa, with the object of studying the natural history of the country, especially the plants and insects. Mr. Cook will be glad to hear from anyone who would like to have material from that region.

YESTERDAY evening a meeting of the Medical Society, University College, London, was held in the Botanical Theatre, University College. Dr. W. H. Gaskell, F.R.S., delivered an address on a new theory of the origin of Vertebrates, deduced from the study of vertebrate anatomy and physiology.

THE Belgian Minister of Public Instruction offers a prize of 25,000 francs for the best memoir on the meteorological, hydrological, and geological conditions of the countries of equatoria Africa, regarded from the sanitary point of view. The subject must be studied with special reference to the welfare of Europeans resident in the Congo State.

IN the Proceedings of the Academy of Natural Sciences of Philadelphia for 1891, some parts of which have just reached us, there is an excellent memoir of the late Dr. Joseph Leidy, by Dr. Henry C. Chapman. It is followed by a list of Dr. Leidy's numerous writings.

IN a valuable paper on the "Rapakiwi," J. J. Sederholm, o the Geological Survey of Finland, has furnished petrographers with a trustworthy description of the mode of occurrence and minute structure of a granitic rock which has excited much interest, but has hitherto been very imperfectly understood. The official maps of the district where the Rapakiwi is found, with the accompanying memoirs, were published about a year ago; and the last number of Tschermak's *Mineralogischen und Petrographischen Mittheilungen*, now edited by Dr. F. Becke contains a full discussion of the petrological peculiarities of the rock. Writing from the famous laboratory of Heidelberg, Herr Sederholm naturally adopts the nomenclature of Prof. Rosenbusch, and it would appear from his description that the Rapakiwi will have to take its place among the numerous types of "granophyre" (using this term as Rosenbusch does, and not as originally defined by Vogelsang) which constitute links between the plutonic granites and the volcanic rhyolites. The excellent photographic illustrations accompanying the memoir give an admirable idea of the peculiar nodular structure of the rock, which has attracted so much attention to it. In the same journal, we find a second memoir by Herr Sederholm, on the Archæan rocks of South-West Finland, describing a varied series of igneous rocks, and discussing the effect of dynamo-metamorphic action upon them. The general conclusions of the author agree with those to which the study of similar rocks in other districts has led Lossen, Roland, Irving, Lehmann, Williams, Reusch, and Teall.

EXCELLENT arrangements have been made for the establishment of a good system of technical instruction in Essex. An organizing joint committee of the County Council and the Essex Field Club was lately appointed to deal with the question, and funds were placed at its disposal. This body has now issued a preliminary schedule of subjects to be taught. Local technical instruction committees are invited to select from the list one or more subjects which they may deem specially suitable for their respective neighbourhoods. When several such bodies, representing adjacent districts, have chosen a particular subject, the organizing committee will select a teacher or lecturer, and endeavour to arrange a circuit for him comprising the centres needing his services, apparatus and illustrations being provided by means of the fund for that purpose. By this means the aid of thoroughly qualified and equipped instructors may be obtained by the local committees at a cost considerably less than would be incurred if each centre were to act independently.

STRENUOUS efforts are being made in Scotland to secure that the country shall be supplied with a sound and adequate system of technical instruction. An important public meeting will be held at Edinburgh, on Thursday, October 29, for the consideration of the subject. Lord Elgin will preside, and it is expected that several members of both Houses of Parliament, and others interested in the question, will take part in the proceedings. The following are the provisional agenda:—(1) Chairman's address; (2) report on action taken up to this time by Town and County Councils—(*a*) in England, (*b*) in Scotland—with reference to the application of the sums available for technical education under the Local Taxation (Customs and Excise) Act, 1890; (3) the relation of the Local Taxation Act to technical (including commercial and agricultural) education; (4) report on various agencies already available for technical instruction in Scotland—(*a*) in rural districts, (*b*) in towns; (5) the amendments necessary in the Technical Schools (Scotland) Act, 1887.

THE Nicholson Institute, Leek, of which Sir Philip Magnus is President, has issued its Calendar for the session 1891–92; and an admirable Calendar it is, presenting many varied elements of interest. In the technical school connected with the Institute there will be classes for the study of wood-carving, modelling, bleaching, hygiene, and other subjects; and in the "science department" instruction will be given in botany, physiology, physiography, machine construction and drawing, and practical plane and solid geometry.

AN Agricultural and Mechanical College is about to be established at São Paulo, in Brazil, an endowment of 200,000 dollars having already been promised, and the further aid of the Government secured. The Presidency of the College has been offered to Prof. L. H. Bailey, the American botanist.

IN the Report for 1891 of the Governors of the Baltimore Fishing School, an interesting sketch of the history of the institution is given. The progress of the school encourages the Governors to believe that its success will prove of great advantage to Irish fisheries. They point out, however, that its operations are not on the enlarged scale originally contemplated; and to all who can appreciate the importance of the youth of the Irish coasts being trained in remunerative industrial pursuits, the Governors appeal for contributions to enable them to extend their work. The boys are thoroughly instructed in everything that pertains to the labours of fishermen. They also receive the literary education usual in such establishments; and a special class has been formed for the teaching of elementary navigation in connection with the Science and Art Department. At the last examination in this subject twenty-four pupils presented themselves. Of these, not one failed, twenty-two passing in the first division, and two in the second.

WE have received from the Meteorological Council a copy of the "Meteorological Observations at Stations of the Second Order" for the year 1887, containing observations and results for 66 stations. At 21 stations the observations taken at 9h. a.m. and 9h. p.m. are printed *in extenso*, and the whole work is on the same plan as in the volume for 1886 (NATURE, vol. xliii. p. 20), viz. the barometer observations are given without reduction to sea-level, and the differences between the dry and wet bulb thermometer readings are given as the "depression of wet-bulb." The maximum and minimum thermometers are read at 9h. p.m., and the readings entered to the day on which they were read. The rainfall is measured at 9h. a.m., and the amount registered entered to the previous day. Fog is only entered when the observer is quite enveloped in it. This work has been continued in a more or less complete form since 1866 (when, however, there was only one station); and the summaries contain, *inter alia*, very useful *résumés* of the state of the weather and wind-distribution, and afford excellent materials for preparing a revised climatology of the British Isles. The work is accompanied by a key map, showing the distribution of the stations, and indicating those which belong to the Royal and Scottish Meteorological Societies: it will be seen that all districts are well represented except, perhaps, on the more exposed western coasts and islands. A special table is also given, showing the number of hours of bright sunshine in each month for those stations at which sunshine-recorders exist.

THE Chief Signal Officer of the U.S. Army has, just before the transfer of the Meteorological Service to the Agricultural Department, issued three atlases, bearing upon the meteorology of the United States, showing—(1) The isobars, isotherms, and winds for each month from January to December for the years 1871–73, a period prior to the regular publication of the monthly charts. The data used include all the materials possessed by the Smithsonian Institution. (2) The probability of rainy days, prepared from observations for 18 years (1871–88). The average number of such days for all months and for each station has been calculated, and the percentages thus obtained are graphically shown on the charts. The data show great differences of distribution of rainfall in localities not far distant from each other; the influence of the prevailing direction of the wind in increasing the number of rainy days is particularly noticeable in the Lake region. (3) The average monthly cloudiness for the period 1871–88. Cloud observations show indirectly the relative amount of sunshine, as it may be assumed, within reasonable limits, that the complement of cloudiness will be sunshine. The investigation of this element is useful in determining the suitableness of certain localities for health resorts, or for the ripening of crops, and the charts may be considered as standard cloud maps of the United States.

DR. KING, Director of the Botanical Survey of India, has issued a Report on the working of the Botanical Survey in Assam and Burmah, for which 2000 rupees are annually allowed, with a view to arranging a plan for working by native collectors. Dr. King visited Assam in the latter half of last year, and found the local authorities ready to afford every assistance. Two native collectors were secured, and set to work near Golaghat, and in the Khasia Hills. The Conservator of Forests also sent a large number of specimens to the Herbarium at Calcutta, and a Eurasian collector was employed for a time in Cachar. Some interesting plants were also obtained from the base of the Eastern Himalayas. Fairly good work was done in Upper Burmah by a native collector, and his specimens are now in course of being arranged at the Calcutta Herbarium. The collecting agencies continue working during the present year.

DR. PRAIN, the Curator of the Herbarium of the Calcutta Botanical Gardens, accompanied the surveying ship *Investigator* during part of her operations in the Bay of Bengal last year. By a special arrangement, Dr. Prain was put down on the Great Coco Island for a few days, and was also enabled to pay short visits to the Little Coco and to Rutland Islands. Except for the visit made by Dr. Prain under similar circumstances the previous year, the Great Coco had not before been explored by a botanist, and the Little Coco and Rutland Islands were this year visited for the first time. Accounts of these visits are to be officially published in due course.

A NUMBER of small expeditions in the Chin Hills and on the Bhamo frontier of Upper Burmah have been arranged for next cold season. In the Chin country, a column will explore the Chinboh country, and four other columns will visit the Baunghshe, Tashon, Tlangton, Kanhow, and Nwengal tribes. In order to effect a settlement of the Kachyen tribes, columns will be sent out from Bhamo, Mogoung, and Myitkynia. An expedition will also proceed to explore the amber-mines and the india-rubber tracts, and, if practicable, join hands with Assam.

To estimate the relative merits of different kinds of points for lightning conductors, Dr. Hess recently collected and examined nineteen heads of conductors that had been struck by lightning (*Electrot. Zeits.*). His conclusions are as follows: (1) the fusion of points of lightning conductors by lightning causes no danger of fire through scattering of fused drops, for this does not occur; (2) fine and smooth points receive the lightning stroke in concentrated form, while sharply angled and ribbed, also blunt points, divide it into threads; (3) platinum needles and tips have no advantage over copper points; (4) there are lightning strokes which are capable of making brass wire 7·2 mm. (say 0·29 inch) thick, incandescent. Unbranched copper conductors should therefore never be thinner than 7·0 mm.

IN submitting to the Wellington Philosophical Society some "Coccid Notes" lately, Mr. W. M. Maskell expressed regret that entomologists generally did not devote more attention to the Coccidæ. He believed he was the only person in New Zealand who had published anything on the subject. In the Coccidæ there was infinite variety—a variety of life-history, habits, and customs that seemed greater than that afforded by any other branch of entomology. He gave instances of peculiarities in these insects—wonderful vitality in some cases, and the boring habits of one particular insect after it had thrown off legs, mouth, &c.—all tending to prove that these little despised creatures were more interesting for study than "all the butterflies"

FARMERS in many parts of Victoria seem to be fully alive to the necessity of adapting their methods to the conditions under which they have to carry on their work. Mr. David A. Crichton, in a report printed in the latest Bulletin (No. 12) of the Victoria Department of Agriculture, says that, although farmers are supposed to be too conservative in their practice to do much in the way of new industries, he has been agreeably surprised to find that a very large number are anxious to try crops other than cereals. Fruit culture in particular is attracting great attention, and he feels confident that before long it will become one of the staple agricultural industries of the colony. He is doing his best to stimulate this particular industry, and, in addition to the information afforded by his lectures, he makes it a practice to visit as many places as possible, to advise upon the selection of sites for orchards and vineyards, and give practical lessons in pruning, training, and other matters. He finds that this assistance is highly appreciated, and his services are in great demand in this respect Mr. Crichton's position in connection with the Victoria Department of Agriculture is that of "the fruit and special industries' expert."

MR. JOHN H. COOKE is publishing in the *Mediterranean Naturalist* an interesting series of observations on the geology of the Maltese islands. In the September number he refers to Cala Hein, a little bay between Comino and Cominotto. On a bright day, he says, this bay presents an endless succession of the most brilliant colours, "which commences with a deep blue, and from thence passes through every conceivable gradation of green, orange, and white, after attaining the last of which it again graduates onward in the distance to that cerulean blue that is so characteristic of Mediterranean waters." The setting of the picture is not less effective than the picture itself. Around the bay are many caverns, which have sombre-looking entrances and wildly-fantastic shapes. The sides of these caverns are full of interest for geologists, as "they literally teem with the remains of creatures that formerly lived and died in the waters in which the islands were built up"

MR. W. PRENTIS, of Rainham, Kent, describes in the October number of the *Zoologist* an interesting case of a wild duck's forethought. A mowing machine was set to work round the outside of a field of lucerne bordering a marsh, diminishing the circle each time round the field, leaving about two acres in the centre. A wild duck was seen by the shepherd to fly from the piece of lucerne that was left with something in her beak, and, happening to fly near him, she dropped a three parts incubated egg. She was again observed by the shepherd, and also by the sheep-shearer, carrying another egg in her beak, this time over the marsh-wall towards the saltings; and again she was seen for the third time carrying an egg in her beak in the same direction. Next day, when the field was "finished" by the removal of the last piece of lucerne, the wild duck's nest from which the eggs had been removed was discovered.

MR. W. H. HARRIS, Ealing, records in *Nature Notes* (September 15) a remarkable instance of "frugality" in bees. The recent extremely rainy weather seems to have suggested to his bees that there would probably soon be an end of honey-making. Accordingly, although there was "a crate of fairly filled sections above the stock-box," they adopted vigorous measures to prevent future inconvenience. "It is a positive fact," says Mr. Harris, "that my bees, not content with ejecting larvæ of both drones and workers, proceeded to suck out the soft contents of the corpses, leaving only the white chitinous covering, which had not hardened sufficiently to prevent the workers from piercing it with their mandibles, and then inserting their tongues."

MESSRS. R. FRIEDLÄNDER AND SON, Berlin, send us the latest of their catalogues of botanical books. This list, besides various works on the distribution of plants and on botanical exploration, includes a great number of writings on the floræ of different parts of the world.

MESSRS. KEGAN PAUL, TRENCH, TRÜBNER, AND CO. announce the following books on scientific subjects:—"Colour Blindness and Colour Perception," by F. W. Edridge-Green, M.D., with three coloured plates (International Scientific Series); "Descriptive Catalogue of the Nests and Eggs of Birds found breeding in Australia and Tasmania," by A. J. North, with 21 full-page plates; "English Folk Rhymes," by G. F. Northall; the following volumes of a series, "Modern Science," to be edited by Sir John Lubbock—"The Cause of an Ice Age," by Sir Robert Ball, F.R.S., "The Horse: a Study in Natural History," by William Henry Flower, C.B., "The Oak: a Popular Introduction to Forest Botany," by H. Marshall Ward, F.R.S., "The Laws and Properties of Matter," by R. T. Glazebrook, F.R.S.;—"On Seedlings," by Sir John Lubbock, with numerous figures in text; "How to Use the Ophthalmoscope," elementary instruction in ophthalmoscopy, by Edgar A. Browne, fourth edition, completely revised; "Principles of Political Economy," by Arthur Latham Perry; "Moral Order and Progress," an analysis of ethical conceptions, by S. Alexander, second edition (Trübner's Philosophical Library); "Chemistry of the Carbon Compounds, or Organic Chemistry," by Prof. Victor von Richter, authorized translation by Edgar F. Smith, new and enlarged edition.

TWO more papers by Prof. Curtius, upon the reactions of the hydrate of his recently isolated hydrazine or diamidogen, $\begin{matrix}NH_2\\|\\NH_2\end{matrix}$, are contributed to the most recent numbers of the *Journal für praktische Chemie*. The earlier communication describes, for the first time, the neutral sulphate of hydrazine

$(N_2H_4)_2 \cdot H_2SO_4$. Hydrazine is found to form two sulphates—an acid one, $N_2H_4 \cdot H_2SO_4$, and the neutral one now described. The acid sulphate is a beautifully crystalline salt—an account of which was given in Nature, vol. xliii. p. 205. It is distinguished by its high melting-point, 254° C., and its difficult solubility. The neutral sulphate now described is obtained by evaporation of the solution formed by neutralizing hydrazine hydrate with dilute sulphuric acid, first, over a water-bath, and finally, as the new salt is very deliquescent, *in vacuo*. It crystallizes in large brilliant tables, melting at 85°. It is precipitated in a most curious manner from its aqueous solution by alcohol, separating as an oil, which, on being stirred with a glass rod, and in contact with a small crystal of the salt, immediately solidifies to a fine mass of crystals, which, like those obtained by evaporation, consist of anhydrous $(N_2H_4)_2 \cdot H_2SO_4$.

The second and much longer communication describes an important series of new compounds, the ketazines, obtained by the action of hydrazine hydrate upon ketones. The simplest of these new substances, the one obtained by the action of hydrazine hydrate upon acetone, is represented by the formula  $\begin{matrix}CH_3\\CH_3\end{matrix}\!>\!C{=}N{-}N{=}C\!<\!\begin{matrix}CH_3\\CH_3\end{matrix}$. When hydrazine hydrate is dropped upon acetone, a most violent reaction occurs, resulting in an explosion unless the acetone is surrounded by a freezing mixture. When thus moderated, however, the substance above formulated is produced together with water, the reaction occurring according to the following equation:—

$$2\begin{matrix}CH_3\\CH_3\end{matrix}\!>\!CO + N_2H_4 . H_2O = \begin{matrix}CH_3\\CH_3\end{matrix}\!>\!C{=}N{-}N{=}C\!<\!\begin{matrix}CH_3\\CH_3\end{matrix} + 3H_2O.$$

By allowing the product to remain for some hours in contact with caustic potash the water is removed, and upon distillation the new ketazine passes over in the pure state. It is a clear liquid possessing a sharp odour somewhat resembling that of the alkaloid coniine. It boils without decomposition at 131°. By employing other ketones, such as methyl ethyl ketone, diethyl ketone, and others of the same type, a large number of these ketazines have been prepared. Those containing fatty radicles are liquids, and those containing aromatic groups are solids. The lowest members only dissolve in water, the solubility rapidly diminishing with increase of carbon atoms. Acids decompose them in the cold, with assimilation of water, into their constituents; towards alkalies, however, they are comparatively stable. Light exerts a decomposing action upon them, specimens placed in bright sunshine rapidly becoming yellow. Reducing agents, such as sodium amalgam, are without action upon them, and they appear further to be incapable of reducing either Fehling's solution or (except after long boiling) ammoniacal solutions of silver salts.

The additions to the Zoological Society's Gardens during the past fortnight include two —— Cormorants (*Phalacrocorax*, sp. inc.) from New Zealand, presented by the Earl of Onslow, G.C.M.G.; a Velvet Monkey (*Cercopithecus lalandii* ♀) from South Africa, a White-fronted Lemur (*Lemur albifrons* ♀) from Madagascar, presented by Captain R. C. Stevenson; a Golden Agouti (*Dasyprocta agouti*), a Garden's Night Heron (*Nycticorax gardeni*), a —— Heron (*Ardea*, sp. inc.) from Surinam, presented by Mr. Frank Fisher; a Common Paradoxure (*Paradoxurus typus*) from India, presented by Miss Bason; two Blackcaps (*Sylvia atricapilla*), two Lesser Whitethroats (*Sylvia curruca*), two Goldfinches (*Carduelis elegans*), a Marsh Tit (*Parus palustris*), British, presented by Mr. J. Young, F.Z.S.; three Common Vipers (*Vipera berus*), British, presented by Messrs. A. H. R. and F. R. Wollaston; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mrs. Gwynne; an Indian Civet (*Viverricula malaccensis*) from India, presented by Mr. Herbert Courtney Hodson; two Chilian Sea Eagles (*Geranoaëtus melanoleucus*) from Chili, presented by Mr. H. Berkeley James, F.Z.S.; two Grey-breasted Parrakeets (*Bolborhynchus monachus*) from Monte Video, presented by Mr. J. C. Wallace; two Nightingales (*Daulias luscinia*), two Common Whitethroats (*Sylvia cinerea*), a Blackcap (*Sylvia atricapilla*), British, presented by Mr. J. Young, F.Z.S.; four Yellow Wagtails (*Motacilla raii*), British, presented by Mr. W. Swaysland; a Common Cormorant (*Phalacrocorax carbo*) from Scotland, presented by Mr. F. T. Barry, M.P.; fifteen Striped Snakes (*Tropidonotus sirtalis*) from North America, presented by Mr. J. Gray; a Solitary Thrush (*Monticola cyanus*), European, a Macaque Monkey (*Macacus cynomolgus*) from India, deposited; a Sharpe's Wood Owl (*Syrnium nuchale*) from West Africa, a Testaceous Snake (*Ptyas testacea*) from California, two Quebec Marmots (*Arctomys monax*) from North America, two Scaly Doves (*Scardafella squamosa*) from South America, purchased; a Ruddy-headed Goose (*Bernicla rubidiceps*) from Falkland, received in exchange.

OUR ASTRONOMICAL COLUMN.

Physical Appearance of Periodic Comets.—Comets possess no personal characteristic appearance; but Mr. Barnard, writing to the *Astronomical Journal*, No. 246, suggests that it may be possible to arrange those of short period according to their physical peculiarities. To the first class he would assign those comets which are large, round, and very gradually brighter in the middle, with no special condensation, and of a very diffused nature. They have no nucleus or tail, and are so decidedly periodic that, trusting to this peculiarity, Mr. Barnard predicted that the comet discovered by Swift in November 1889, and D'Arrest's comet at its return last year, were of short period. The most distinctive members of this class of comets are D'Arrest's, Swift's 1880, Brooks's 1886, and Swift's 1889. There are few nebulæ that resemble this class. A much larger and less exclusive class contain comets which are comparatively small, and which have an indefinite central brightness or nucleus. Many of the parabolic comets resemble these, and there are hundreds of nebulæ exactly like them in telescopic appearance. To this class are assigned comets Faye; Wolf, 1884 III.; Finlay, 1886 VII.; Brooks, 1889 V.; Spitaler, 1890. It is possible that the peculiarities of these two distinct classes of short-period comets may furnish some information as to their relative ages.

Discovery of Tempel-Swift's Comet.—Mr. Barnard found this comet on September 28, and Mr. W. F. Denning discovered it independently two days later about 4° south-west of its computed position. The comet passes perihelion in November. Its position, according to M. Bossert's ephemeris, is as follows:—

Ephemeris for Paris Midnight.

1891.	Right Ascension.			Declination.		Brightness.
	h.	m.	s.	°	′	
Oct. 6	21	6	2	+ 3	24·8	7·01
„ 8		6	19	3	54·0

The comet is therefore in Equuleus at the present time, and moving towards Pegasus.

PHOTOGRAPHIC DEFINITION.

I.

It is a matter of some interest to determine what are the limits to the definition obtainable in photographs. In examining this question, three distinct classes of problems present themselves—namely :—

(1) Those depending on the wave-length of light, and the action of a perfect lens on such wave-lengths.

(2) The various aberrations of real lenses.

(3) The qualities of the different sensitive surfaces on which the pictures are formed.

Taking these divisions of the subject in the order given, I will inquire first what is the limit to photographic definition on the supposition that the lens has no aberration of any kind, *i.e.* that all the waves which reach it from any point arrive at the image of that point in the same phase.

The image thus formed consists, as is well known, of a bright disk surrounded by alternate dark and bright rings, the intensity of the illumination of the rings decreasing rapidly at each successive ring, reckoning outwards from the centre.

In order that the images of two neighbouring points may appear separated from one another, the central disks of their images ought not to overlap. If the disks are just in contact, it is possible that they would appear as a double object in the photograph, and this may be taken as the limit of the defining power of a lens. (See Airy "On Light," and Lord Rayleigh "On the Theory and Manufacture of Diffraction Gratings," *Phil. Mag.*, 1874.)

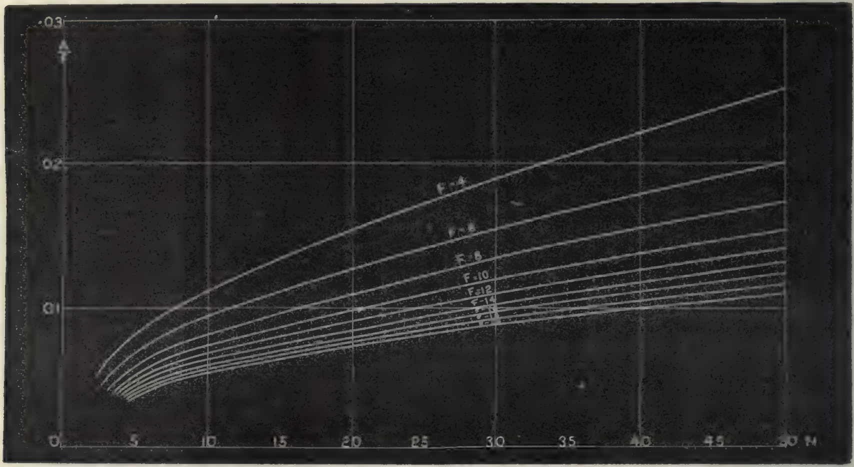

Fig. 1.

But, in ordinary photography, objects at very various distances have to be simultaneously represented, and it is to the definition attainable under these circumstances that I wish now to direct attention.

On referring to the papers above-mentioned, it will be seen that the diameter of the central disk is

$$1{\cdot}219\,\frac{\lambda F}{A},$$

where λ is the wave-length of light,
F the focal length of the lens,
A the aperture of the lens.

This gives the effective diameter of the image of a point truly in focus when not far removed from the axis of the lens.

Points nearer to, or further from, the lens than that which has its image on the plate will be represented on the latter by round patches of light ; these being the sections by the plate of the cones of rays which have for their summits the geometrical foci of the points, and for their slant the radius of the aperture ÷ focal length.[1] Thus, if e is the distance before or behind the plate of the focus of a point, it will be represented on the plate by a patch of light of diameter

$$e\,\frac{A}{F}.$$

This diameter can be diminished by the use of a diaphragm, *i.e.* by diminishing A, but this at the same time increases the diameter of the images of points whose foci are on the plate. And the resulting average definition will be improved by diminishing A until the patch of light, representing the point most out of focus, has the same diameter as the diffraction disk of the image point in focus.

If we suppose the photographic plate to be placed at such a distance from the lens that the focus of the nearest object is as much behind the plate as the focus of very distant objects is in front of it, we shall have, to determine the diameter of the stop giving the best average definition, the following equation :—

Putting F = principal focal length,
D = distance of nearest object,
$q = 1{\cdot}219\lambda$,

$$q\,\frac{F+e}{A} = e\,\frac{A}{F+e}\,;$$

$$\therefore\quad q\,\frac{(F+e)^2}{e} = A^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

but, by the ordinary formulæ, connecting the conjugate foci of lenses, we have, if $D = F + g$,

$$2eg = F^2\,;$$

$$\therefore\quad e = \frac{F^2}{2g} = \frac{F^2}{2(D-F)}\,;$$

---

[1] This is an approximate statement only. The true expression involves an investigation of the intensity of the light immediately in front of and behind a caustic.

whence, substituting for e in (1) we have

$$A = \sqrt{\frac{q}{2}}\,\frac{2D - F}{\sqrt{D - F}}\ .\ .\ .\ .\ .\ .\ .\ (2)$$

Let the nearest object be at n times the focal length of the lens. Then, putting nF for D,

$$A = \sqrt{\frac{qF}{2}}\,\frac{2n - 1}{\sqrt{n - 1}}\ .\ .\ .\ .\ .\ .\ (3)$$

This gives the value of A as a linear quantity; it is usual, however, to reckon the diameter of stops as fractions of the focal length.

Dividing, therefore, (3) by F,

$$\frac{A}{F} = \sqrt{\frac{q}{2F}}\,\frac{2n - 1}{\sqrt{n - 1}}\ .\ .\ .\ .\ .\ .\ (4)$$

From (4) the accompanying table has been computed, giving $\frac{A}{F}$ for various values of F and n. (Fig. 1 gives the same graphically.)

Table showing ratio of aperture to focal length which gives the best average definition when the nearest object to be photographed is at "n" times the focal length of the lens, and distant objects are a'so in view.

F	$\frac{A}{F}$ n=5	n=10	n=15	n=20	n=25	n=30	n=35	n=40	n=45	n=50

16	·00392	·00552	·00651	·0076	·0085	·0093	·0101	·0108	·0115	·0122
18	·00370	·00520	·00615	·0071	·0080	·0088	·0095	·0102	·0109	·0115
20	·00350	·00494	·00584	0068	0076	·0084	·0090	·0097	·0103	·0109

I have not before seen it pointed out that the ratio $\frac{A}{F}$, which gives the best average definition, alters with the value of F.

If α is the least angular distance between two points (as seen from the centre of the lens) which are shown as separate points on the photograph, α must at any rate not be less than $\frac{q}{A}$, or

$$\sqrt{\frac{2q}{F}}\,\frac{\sqrt{n - 1}}{2n - 1},$$

showing that, if the foreground is kept at a distance proportional to the focal length of the lens, the definition improves with an increase of the focal length.

On the other hand, if the nearest object is at some fixed distance, D, from the lens, we have as the limit for α,

$$\sqrt{2q}\,\frac{\sqrt{D - F}}{2D - F},$$

an expression which increases with F, so that for a given picture taken from a fixed position, definition will be gained by the use of a short focus.

The gain, however, in this respect is not great, for in practice D is always a considerable multiple of F, and writing

$$\sqrt{\frac{1}{4D + \frac{F^2}{D - F}}}\ \text{for}\ \frac{\sqrt{D - F}}{2D - F},$$

it will be seen that when D is many times F, $\frac{F^2}{D - F}$ may be neglected in comparison with 4D.

Thus, in ordinary cases the limit for α is $\sqrt{\frac{q}{2D}}$, and is independent of the focal length of the lens employed.

If we inquire how close the nearest object may be to the lens when a view containing also distant objects has to be photographed with a definition reaching a certain standard, we have, on the above supposition,

$$D = \frac{q}{2\alpha^2};$$

and if we put $\alpha = 1'$, which is often taken as the least angle separable by the unaided eye, and λ as $\frac{1}{50000}$ inch,

$$D = 150 \text{ inches},$$

showing that if the picture is to appear as well defined as the natural objects themselves, to the eye placed at the position of the lens, no object in the view must be nearer the latter than about 13 feet.[1]

Though, as above stated, the focal length does not affect the definition, when the right-sized stop is used, it does the rapidity with which a picture may be taken, for the intensity of the light on the plate is measured by $\frac{A^2}{F^2}$ or $\frac{q}{2F}\,\frac{(2n - 1)^2}{n - 1}$.

That is, in these circumstances, the exposure is inversely as the focal length.

All that has been hitherto said refers to the definition in the central parts of the plate.

The definition for the oblique pencils is necessarily worse. For even if it were assumed that the lens was perfect for oblique pencils, the points out of focus would be no longer represented by circular areas, but by the elliptic projections of these circles on the plane of the plate.

The assumption, however, that a lens is perfect for oblique pencils is too far removed from actual fact to make it worth while to consider the results to which such a supposition would lead.

The definition for the marginal parts of the photograph depends on the various aberrations which all combinations of lenses suffer from in some degree, but which in well-made examples are completely, or almost completely, corrected for direct pencils.

These aberrations are (1) spherical, (2) chromatic, (3) astigmatism, (4) curvature of field.

The effects of the two last are much the most important, and will be considered first.

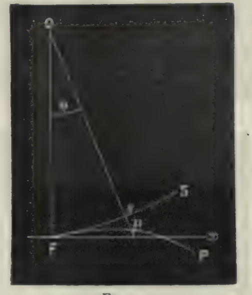

FIG. 2.

Let O (Fig. 2) be the optic centre of the lens, OF the axis of the lens, and F the principal focus.

Let Fx be the plane of the plate, FP and FS the curves on which the primary and secondary foci respectively lie.

Let Op be the axis of a pencil inclined to OF at an angle θ, and meeting FP and FS in p and s. Then sp measures the astigmatism of the lens for a pencil of obliquity θ.

Putting y_p and y_s for the ordinates of the curves FP and FS at p and s, it will be seen that a point distant θ from the axis of the lens, will be represented on the plane of the plate by an oval patch of light whose axes are $A\frac{y_p}{\cos\theta}$ and $A\frac{y_s}{\cos\theta}$ in directions parallel and perpendicular to Fx; A, as before, being the aperture of the lens.

Any formula depending on the actual data of real combinations of lenses, and giving the values of y_p and y_s in terms of radii of curvature and refractive indices, &c., of the lenses composing them, would be a very unmanageable thing for the purpose in hand; but I give the curves in question obtained experimentally for seven lenses of different types in my possession (see Figs. 3 to 9). All these lenses except Fig. 5 are by makers reputed to be the best.

---

[1] I have verified this with a lens of 10-inch focus.

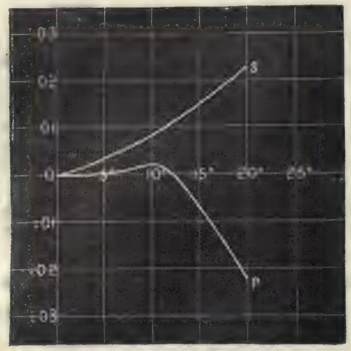

Fig. 3.—English Portrait.

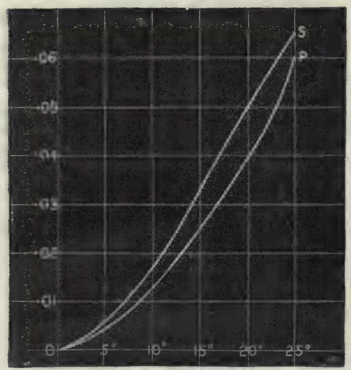

Fig. 4.—English Portrait.

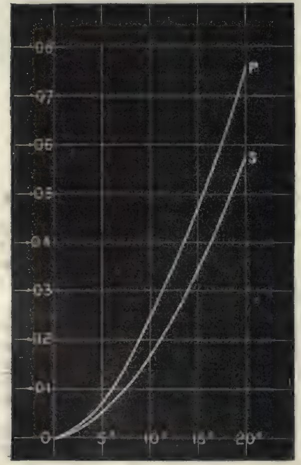

Fig. 5.—French Portrait.

[Fig. 5 is peculiar in having the usual relative positions of the primary and secondary foci reversed.]

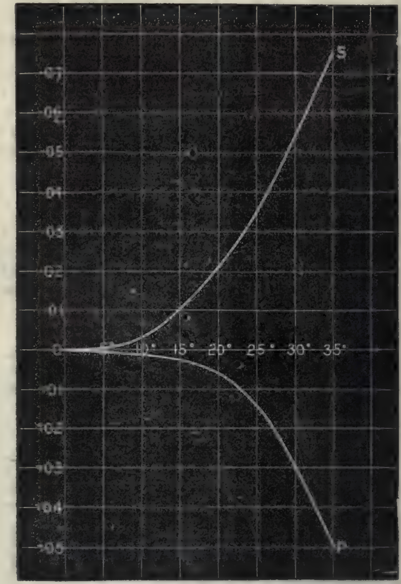

Fig. 6.—English Wide-angle Doublet.

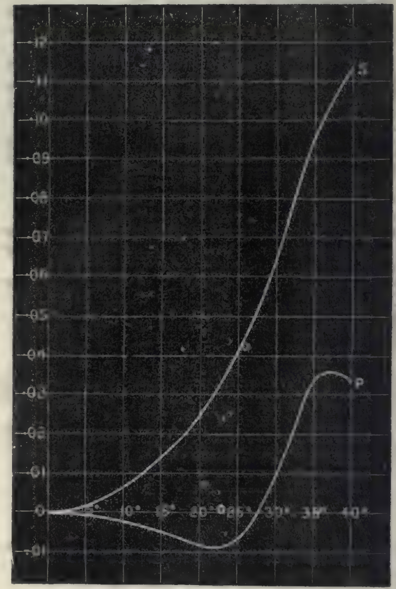

Fig. 7.—French Wide-angle Doublet.

The ordinates of these curves are the distances of the primary and secondary foci from a plane through the principal focus at right angles to the axis of the lens, and are expressed as fractions of the focal length.

The abscissæ are the inclinations (in degrees) of the pencils to the axis

Suppose, now, that the plate is placed at a distance e behind

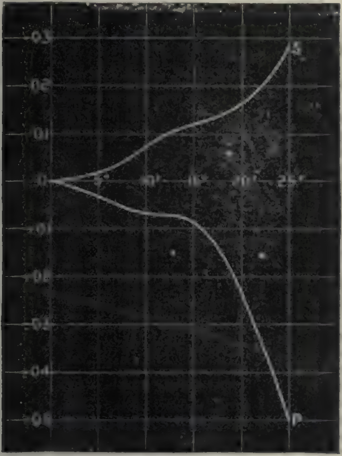

FIG. 8.—Rapid Rectilinear.

the principal focus, e being half the distance between the foci for direct pencils of the nearest and distant objects.

The worst defined point in the centre of the picture will then be represented as having a width $\frac{A}{F}e$ nearly, while at the obliquity θ this width becomes $\frac{A}{F}\frac{e \pm y}{\cos\theta}$ nearly, according to whether the

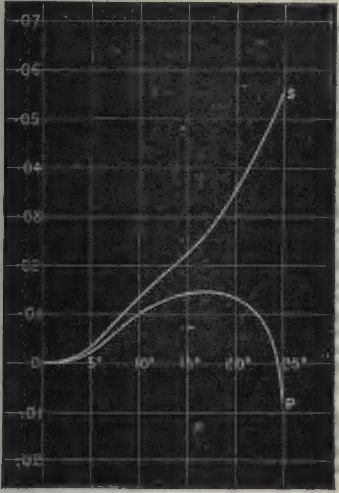

FIG. 9.—Triplet.

image under consideration is that of the most distant or the nearest point.

Hence, unless y is small compared with e, the definition for rays of obliquity θ will be sensibly worse than in the centre of the plate, and a reference to the curves for y_p and y_s shows at a glance that this must be the case even at 10° for all the lenses unless the general standard of the definition is lowered by a large value of e.

As an example of the use of the curves, let us take the rapid rectilinear No. 6, and compare the definition at 20° obliquity with that at the centre, supposing that the nearest object is at a distance of 25F.

This gives $e = {·}02$F nearly, and at 20° $y_p = -{·}023$F, $y_s = +{·}016$ F, hence we have as follows:—

		At 20° from axis		
		due to primary focus.	due to secondary focus.	At centre.
Width of image of				
nearest point...	$\frac{A}{F\cos\theta} \times$ ...	·043 ...	·004 ...	·02
Distant do.	...	·003 ...	·036 ...	·02

This shows that while the nearest points at this obliquity are represented by long ovals placed as if radiating from the axis, the most distant points become similar but rather smaller ovals with their long axes at right angles to the former, and that the length of the ovals is about twice the diameter of the image formed by the direct pencils.

In the same way the definition, as far as it depends on astigmatism and curvature of field, at any obliquity may be found for any lens for which y_p and y_s are known.

Lauriston Hall, September 9. A. MALLOCK.

(*To be continued.*)

THE KOH-I-NUR—A CRITICISM.

THE true history of the Koh-i-Nur diamond, if it could be written, would be a singularly interesting one. But the historian would have a difficult task. The pages that I purpose writing will be devoted to the criticism, possibly the refuting, of some fallacies that hang round the subject; but they will not deal with some other historical difficulties that I have not space even to indicate, but which do not belong to those portions of the history for criticism on which the following pages are designed.

The period in the history of the Koh-i-Nur that has attracted the notice of all modern writers on the diamond, and to a degree, I think, somewhat beyond its importance, is the five or ten minutes during which the French diamond-dealer, Tavernier, held in his hand the most important of the Crown jewels of the Emperor Aurungzebe. It was a great diamond, and the record Tavernier has handed down in his "Voyages," of its weight, its form, and its history, will have to be critically dealt with.

It may be at once stated that the disputable point regarding this diamond is whether it was a certain ancient diamond of fame in India, or one much larger than this ancient stone, that had been found not very long before Tavernier was present at the Court of Aurungzebe. For the larger stone I shall retain the name of "the Great Mogul"; for the older and more famous one the title of the Koh-i-Nur. Some hold that Tavernier saw and handled the Koh-i-Nur; others that his own story is correct, and that it was the Great Mogul that he described. And I should add that some, in addition to this latter view, believe the Great Mogul ought to be called the Koh-i-Nur.

In order to clear the ground, I may say that while attaching no very great importance to the question as to which of the two first views is the correct one—and I must add also, valuing at a somewhat low estimate the historical or technical accuracy of Tavernier's statements on this and many other matters—I, some thirty-five years ago, came to the conclusion that the diamond Tavernier saw was probably the Koh-i-Nur, and that he muddled its history with the other and larger diamond that I showed to have been probably at the time in the keeping of Shah Jahan, the captive father of Aurungzebe. The merits of the question will be discussed in their proper place; but while holding myself open to conviction if any new arguments can be brought forward against my view, I may state that none yet announced have shaken that opinion.

Until the fifteenth century there appears to have been one and only one very large diamond known in India or in the world. I might have said until the sixteenth century but that there is a record of two and an unauthenticated rumour of a third during that century, the largest of which, however, was very likely the Koh-i-Nur. But that one large diamond of the earlier time had been a famous stone for centuries. Legends had gathered round it, and tradition had linked the legends with authentic history in the dawn of the fourteenth century. The tale was told briefly by Prof. H. H. Wilson in the sketch of the Koh-i-Nur which he contributed to the official catalogue of the Exhibition of 1851. No more competent person could have performed the task than the great Orientalist and Sanscrit scholar, with his large experience of Hindoo customs and modes of thought. And he wrote the notice with the statements before him that had been collected in the bazaars of India by order of the Company at the time when the Koh-i-Nur became a Crown jewel of the Queen.

The latest historian of the Koh-i-Nur, however, dismisses this curious tradition and its distinguished narrator by the somewhat flippant remark that "it has afforded sundry imaginative writers a subject for highly characteristic paragraphs."

The gentleman who writes in this tone of the eminent custodian of the East India Company's Library cannot be expected to treat Mr. King or any other man of learning less contemptuously; but his qualifications for dealing with the subject at all from a wider point of view than that of the old French diamond-dealer will, perhaps, be fairly called in question by the readers of the following pages.

Yet Dr. Ball, of the Science and Art Department in Dublin, has had Indian experience on the Geological Survey, an office that ranks deservedly high even among the great departments of the Indian public service. He has, furthermore, recently thought the Indian part of Tavernier's "Voyages" worthy of a fresh translation, which he has effected with judgment and with notes, the topographic part of which, at least, appears to be of considerable value and interest; and he has otherwise been an author on subjects that came before him in India as a geologist and a sojourner.

It is probably a sort of loyalty to the author whom he has deemed worthy of so much of his time and industry that blinds him in his advocacy of Tavernier's statements, notwithstanding their manifold inconsistencies and absence of scholarlike quality. I hope, while criticizing his hypotheses and statements regarding the Koh-i-Nur, I may not in any respect quit a judicial attitude to appear in that of a partisan.

The great diamond to which allusion has been made emerges in history in the first years of the fourteenth century. It was in 1300 A.D. in the hands of the Rajahs of Malwa, an ancient Ráj that had at one time spread over Hindostan, and in all the vicissitudes of a thousand years had never bent to a Muhammadan conqueror, until the generals of the Delhi Emperor Alá-ud-dín Muhammad Shah overran its rich territory, and carried away the accumulated treasure of Ujjein in the first decad of the fourteenth century.

The date of 1304 is that given by Ferishtá for this conquest, and then it was that the great diamond takes its place in history. In 1526 the invasion of India by Babar was crowned by his victory on the famous battle-field of Panaput. Babar himself—in those memoirs that rank only after the "Commentaries" of Cæsar as the most interesting records penned by a great conqueror—describes the reception by his son Humayún of the great diamond among the treasures which he was sent forward to secure at the strong fortress at Agra. Babar gives the weight of the diamond as being computed at 8 mishkals, and in another place he compares the Muhammadan weights with those of the Hindoo system, putting the mishkal as equivalent to 40 of the little Hindoo units of weight, the rati. The diamond, then, weighed near about 320 of these ratis. There are several lines of investigation for determining the weight of the mishkal; and without here entering on a long but interesting discussion of this weight, it will suffice to say that the most important of them converge on a value of from 73 to 74 troy grains. If the mishkal weighed 73·636 troy grains, 8 such mishkals would be 589·088 grains. The weight of the Koh-i-Nur diamond in the Exhibition of 1851 was 589·52 troy grains. It may be added that this latter weight is equivalent to 186$\frac{1}{16}$ English carats of 3·1682 troy grains, and would require, to make up the 320 ratis, a rati of the value of 1·8425 troy grains.

It is very remarkable how numbers closely corresponding to one or other of these values for the weight of a great diamond, in carats or ratis, will recur in the subsequent discussion. Thus Anselm de Boot, in commenting in the early years of the seventeenth century upon some observations on Indian diamonds made in the previous century by Garcias de Orto (a Portuguese physician at the Viceregal Court of Goa), states the largest diamond Garcias had seen to have weighed 187½ carats. Garcias puts its weight at 140 mangelins. His translator (into Latin), Le Cluze, interprets the 140 mangelins as equivalent to 700 grains (apparently French grains of the old poids de marc). But De Boot evidently either had some separate authority for his statement that the largest diamond Garcias had seen weighed 187½ carats, or had the means of reckoning more correctly than Le Cluze the value in Dutch or in Portuguese carats of the 140 mangelins of Garcias. Garcias was in India for thirty years in the reign of Akbar, a reign that, commencing three years earlier and ending three years later, covered "the spacious times of great Elizabeth"; and if any European of the many visiting India at that time would have had special opportunity of seeing the great diamond in the treasury of Babar's grandson, it would have been the body-physician of the Portuguese Viceroy. Dr. Ball has got into a hopeless mess in an endeavour to discredit observations of mine, and of my late learned friend Mr. King, regarding this allusion of De Boot's to a diamond weighing 187½ carats. Dr. Ball is quite mistaken in supposing that he is the first person who had an acquaintance with De Boot's sources of information, with Le Cluze's translation of Garcias into excellent Latin, and with the commentators who edited De Boot and largely plagiarized from Le Cluze. In his "Natural History of Precious Stones," Mr. King gave, in 1866, an account of all these persons and their writings, but that accomplished scholar would certainly never have fallen into so absurd an error as Dr. Ball has rushed into in connection with De Boot's allusion to a 187½-carat diamond.

Garcias, like Le Cluze, was a botanist, and his treatise was on Indian botany. He, however, devoted a few pages to the precious stones in vogue in India, and one short chapter is given to the diamond. De Boot transcribed, with omissions, these chapters of Garcias, and with misprints that probably arose from the statements he made, and even the pages he incorporated, being in the form of notes culled by him from a great variety of sources, of which Garcias was only one. Among the misprints or misapprehensions in De Boot's very remarkable book on stones and gems, is that by which he always substitutes the name of Monardes, a writer on the botany of the New World, in lieu of that of Garcias, an error the source of which Mr. King explained in the treatise above alluded to. Upon the passage in which De Boot refers to the great diamond, and which runs thus: "Nunquam tamen majorem (adamantem) illo qui pendebat 187½ ceratia, cujus mentionem facit Monardes, inventum fuisse puto," Adrian Tull, a Belgian physician who edited the treatise of Anselm de Boot, adds a note to the chapter, correcting the name Monardes for that of Garcias, and then quoting from Le Cluze another note introduced at the end of his translation of the chapter, to the effect that he, Le Cluze, had never himself seen a larger diamond *in Belgium* than one which weighed 190 *grains*. Dr. Ball quotes this note in the Latin of Le Cluze to show that De Boot did not know what he was writing about, and still less that Mr. King and, of course, myself did, inasmuch as we had fastened upon De Boot's singular statement without due study of our authors. It is the writer of the "true history" of the Koh-i-Nur who has not gone to the authorities. Had he done so, he would have found in the 1605 edition three notes on this passage by Le Cluze. In the first he analyzes Garcias's 140 mangelins into "septingenta grana, sive unciam unam, drachmam unam, scriptula duo, grana quatuor. Nam mangelis, ut ante dixit noster auctor, quinque grana pendit, et septuaginta duobas granis dragma constat." His next note alludes to the diamonds he had seen himself in Belgium; and the third is upon certain crystals known as Bristol diamonds, found three miles from that city.

Passing from this curious aberration of Dr. Ball's, we may ask, What did De Boot mean by alluding in a second passage to the diamond Garcias had seen in India as weighing 187½ carats? As I have said, it is barely possible he had means external to Garcias's statement in his book of knowing the weight of this diamond. The weights summed together by Le Cluze were apothecary weights, varying somewhat in different localities in Western Europe from the corresponding divisions of the French ounce of 576 French grains, equivalent to 472·1875 troy grains. The weight of the diamond on the French system would be 573·776 grains troy according to Le Cluze's reckoning, In terms of the old Netherlands ounce of 474·75 grains, current in Antwerp, it would be 576·95 troy grains. But none of these are carat grains. De Boot, on the other hand, in estimating the 140 mangelins as 187½ carats, took the mangelin not at the 5 carat grains of Garcias, but at 5·3568 such grains, taking probably 1⅓ carat as the measure of the mangelin instead of 1¼ carat, the former being one among the several values which this variable unit had in different places.

The 187½ carats of De Boot would, on the value of the Amsterdam carat, 7½ of which equal an engle, which was the sixteenth part of the Dutch troy mark, give a weight for the diamond in question of 593·437 troy grains: the weight of the Koh-i-Nur having been 589·5 troy grains. It is very difficult to ascertain with accuracy the values of the different units—marks, ounces, carats—in the different countries and cities in the seventeenth century; but it is probable that even the mere 4 grains, or little more than a carat, difference between De Boot's estimate of the 140 mangelins and the traditional weight of the Koh-i-Nur would disappear if we possessed these data in a more complete form. There can be little doubt that Le Cluze was in error in taking the apothecary weight instead of carat weight in translating the grains of Garcias.

It may be asked, Why devote so much consideration to this casual statement of De Boot's? The answer is twofold. The astronomer has patiently searched in the records of early observations for any that might indicate the position at a former epoch of a new-found planet; and so, where the silence about an object of historical interest has been scarcely broken through two or three centuries, one tests any observation of the casual wayfarer in the domain of literature that may perhaps shed a ray of light on it. The other reason is that, if not disposed to resent, one is at least desirous to refute, attack on those who can no longer give their own answer to assailants of a new generation, who perhaps may not bring to an investigation the learning or the patient temper of those who have gone from us, and carried great stores of scholarly learning into the silence. Whether I am right or wrong in the explanation I have offered of De Boot's conversion of Garcias's 140 mangelins into 187½ carats, I trust that at any rate I have shown cause for the statement by Mr. King that "it seems as if he (De Boot) had heard of the Koh-i-Nur; it being scarcely probable that two stones should be co-existent of that extraordinary weight."

In dealing with another of those coincidences in weight to which allusion was made, and one example of which has just been discussed, we get on the delicate ground of the degree of confidence to be placed in Tavernier's facts and figures, and the not less delicate ground of a theory about the Koh-i-Nur, started by Dr. Ball, before which the other strange vicissitudes and hairbreadth escapes of that old talisman pale into insignificance.

We have made sufficient acquaintance with the historic Indian diamond to leave it for a while, in order to introduce that other greater stone which we have designated as the "Great Mogul."

Bernier, from personal contact with whom Tavernier no doubt derived much of what had an historical character in his volumes, describes the gift by Emir Jumla, a Persian adventurer of great ability in the service of the King of Golconda, of a large diamond to the Emperor Shah Jahan, "ce grand diamant que l'on estime sans pareil." It was an appeal to his cupidity, and to a real connoisseur's passion for precious stones, at a time when the Emir was effecting a change in his allegiance from Golconda to Delhi—in fact, appealing to a new master to induce him to assail the old one.

In 1665, Tavernier, who was no less a courtier than a dealer, was invited by Aurungzebe to present himself at his Court to inspect his jewels.

The Emperor, seated on the peacock throne, could see the ceremony that was conducted in a small apartment at the end of the hall. Tavernier describes the patient circumspection with which he was shown the various stones and jewels by a Persian custodian. First and foremost among them was the great diamond, "qui est une rose (a rose-cut stone) ronde (rounded but not necessarily circular in form) fort haute d'un côté." There was a small crack at the edge below, and a little flaw within. It was of fine water, and weighed 319½ ratis, which Tavernier states to be equivalent to "280 de nos carats," the rati being ⅞ of a carat, which, however, would give 279·58 carats. Such was the only great diamond that he saw, and as he first described it.

He proceeds to give his version of its history. It was the stone given by the Emir Jumla to Shah Jahan; but he adds that, whereas it had then a weight of 900 ratis or 787½ carats, it was worked down by a Venetian diamond-cutter, Hortensio Borgis, till it had only the 280 carats weight above noted. The word *égrisée* is that used; Dr. Ball interprets it as entirely *ground* down. But, though this is the most rational meaning of this technical word, it would, as Mr. King has remarked, have taken more time than the few months which intervened between the gift and the eclipse of Shah Jahan for the mere grinding down to have been accomplished by the processes in use in the seventeenth century, and especially in India. Undoubtedly, therefore, Hortensio must have availed himself of the cleavage property of the diamond to aid him in his grinding process. Tavernier goes on to say, "Après avoir bien contemplé cette grande pierre, et l'avoir remise entre les mains d'Akel-Kan, il me fit voir un autre diamant," &c., &c.; and he then describes a number of stones and pearls, of which he gives the weights, some more or less approximately, some definitely, in ratis or in melscals (or mishkals). The melscal he also states as giving 6 to the ounce, which I think is probably a mistake for 6½ to the ounce. Finally, he says that he had held all the jewels in his hand, and considered them with sufficient attention and leisure to be able to assure the reader that his description of them is exact and trustworthy, as was that of the thrones which he previously had ample time to inspect. It will be noted he does not say he weighed any of the stones; nor does his doing so seem compatible with his description of the scene.

But in another chapter near the end of the same book he gives a brief enumeration of the finest precious stones he had, in his long travels, known. The diamond described in the earlier chapter is alluded to now with slight but immaterial variations or corrections as to weight; but Tavernier here states that he was allowed to weigh the stone, and he further adds that it had the form of an egg cut through the middle. Dr. Ball truly notes that this process may be performed in one of two ways—longitudinally, or transversely; and that the Koh-i-Nur in 1850 represented the longitudinally bisected demi-egg, but, he naïvely adds, "This difference of form, as I shall explain, was the result of the mutilation to which it was subject."

Tavernier's statement that the diamond was "fort haute d'un côté" seems, indeed, hardly to accord with any other than a longitudinal section of the egg.

But then, as if to make his description inexplicable, Tavernier appends to this later chapter—written or edited probably by another hand four or five years after the event of his handling the stone—a rude sketch of the great diamond that he saw. It may be conceived as an extremely inaccurate sketch from memory of a semi-egg-shaped stone seen "end on," or of a cross-cut half-egg seen from any point of view; but, except for the trace of a small undercut face in his projection, it has not any resemblance to the Koh-i-Nur. In width, his sketch is very slightly larger than the length of the Windsor diamond, but in no other dimension does it at all compare with that stone as it was in 1850.

Then there is the question of weight. Babar's diamond, we have seen, weighed about 8 mishkals, or, in Indian weights, about 320 ratis (gold ratis). This would correspond to 240 pearl ratis, or may be represented as 224 of the Deccan ratis of Ferishtá.

The diamond Tavernier saw weighed, he said (was he merely told so, or did he really weigh it?), 319½ ratis, only half a rati different from Babar's diamond. But Tavernier's ratis were not those which Babar reckoned by, and his carats (*nos carats*) must (*pace* Dr. Ball) have been French carats. Dr. Ball supposes he has contributed to the published data of this tangle of contradictions one new fact in a final determination of Tavernier's carat, and, by implication, of his rati also. Tavernier gives the weight in carats of the yellow diamond of the Grand Duke of Tuscany, now in the Schatzkammer at Vienna. The weight of this stone being accurately known, and being also given by Tavernier as 139½ carats, it is not difficult to determine the value of this particular carat to be 3·037 troy grains. This is in fact identical with the Florentine or Tuscan carat, as Dr. Ball points out.

That gentleman assumes from this that Tavernier always employed this carat in his calculations. Such, however, is quite incompatible with his expression on other occasions, when he speaks of "*nos carats.*" It is clear that Tavernier took the weight of this Florentine diamond from some trustworthy Tuscan source, giving it in Florentine carats. In fact, it is an illustration of what seems to be indicated as his habit in many other instances. He gives the weights of stones he mentions in ratis or mangelins, or in mishkals, and proceeds to state the equivalent weights in terms of *nos carats*, *i.e.* of the Paris carat; for no Frenchman would designate any carat other than one current in France by such a term.

It would be a tedious task to inflict on a reader the minute detail of calculation and reference to statistical authorities that would be involved in a critical study of Tavernier's assertions regarding Indian and other weights, or Dr. Ball's incursion into that study.

But one fundamental error must be alluded to, that vitiates the accuracy of Dr. Ball's calculations. He is possessed of the singular belief that, in the seventeenth century, Tavernier would have been familiar with the French ponderary system known as the *système transitoire* or *usuel*, which was introduced by the law of May 1812 into France, in temporary substitution for the old livre (*poids de marc*) of 9216 French grains, and its subdivisions.

It is quite unnecessary to follow the results of this error; for the only interest as regards our inquiry concerns the significance of the 319·5 ratis which Tavernier states the great diamond of Aurungzebe to have weighed. 320 ratis was the Hindoo equivalent, in Babar's time, of the 8 mishkals of Babar's diamond, and the Koh-i-Nur in 1850 weighed those 8 mishkals.

Tavernier says that the 319·5 ratis correspond to 280 French carats (*nos carats*). Here, then, is a second of those marvellous coincidences in numbers to which we have already made allusion—I may call them impossible coincidences, unless they apply to one and the same diamond.

Dr. Ball sees, apparently, no difficulty in the recurrence of any number of these identical figures as representing the weights of huge diamonds. For his explanation of the matter is that the diamond Tavernier handled was, as the French merchant asserted, the stone that Bernier mentions as the gift of Emir Jumla to Shah Jahan; that it did weigh 319½ ratis, but that these were ratis of Tavernier's standard, equivalent, in fact, to 0·875 of a carat, whereas Babar's ratis were only 0·578 of a carat. Dr. Ball's assertion, however, is that this great diamond is the Queen's Koh-i-Nur, but that after Nadir Shah's time it had become diminished by successive chippings performed on it by needy princes, who in succession owned it, and turned its severed fragments to account, until finally, and presumably before it fell into the hands of Runjit Singh, this great Mogul diamond had shrunk in magnitude from its asserted 280 carats to 186 carats—from the 319½ ratis of Tavernier's reckoning to the 320 ratis on Babar's reckoning; in a word, it had become reduced by this astounding process to the precise 8 mishkals of the Koh-i-Nur in 1526. So here is a third coincidence that we are called on gravely to accept as serious history.

The only originality, however, involved in this singular view of history, and the way to write it, is the reason assigned for the whittling down of the diamond from the asserted 280 carats to 186 carats. Several ingenious persons have indulged before in speculations as to the synthesis of one big diamond to be called the Koh-i-nur from several smaller ones scattered about the world, with a fine scorn of shape and weight and "water" in the component fragments, and of any historical ground whatever for their hypotheses. The late Mr. Tennant, of the Strand, even engaged the services of the great Russian diamond in this mosaic, ignorant, apparently of the facts that, like the Koh-i-Nur, it is an Indian-cut stone of about 194 carats weight, and is of a brownish-yellow hue.

But the coincidences in weight of various phantom diamonds with that which Babar recorded do not come to an end even with this crowning wonder, as I shall presently show.

Perhaps some one may, in parenthesis, ask what evidence there is for the breaking up of a great diamond by owners who clung to the Koh-i-Nur with a tenacity second only to their own hold on life. To this the answer is very simple. Not one fact or plausible argument is adduced to support it. Dr. Ball's imagination is its argument; and, indeed, I cannot find one single contribution of *fact* from that gentleman to the history of the Koh-i-Nur that has any novelty at all. There remains, however, a question that has to be answered, whether this mutilation theory be ever so wild or were ever so sane. If Tavernier saw the Great Mogul diamond, where was the old Hindoo stone? or if it was, as I have supposed, the Hindoo Koh-i-Nur that Tavernier handled, where was the Great Mogul?

Tavernier saw no second diamond of the first rank in magnitude. But there were two great diamonds somewhere—Babar's and Mir Jumla's, or, as I have designated them, the Koh-i-Nur and the Great Mogul. One or other of these Tavernier has described: where was the one he did not see?

It is now thirty-five years ago that I suggested the answer. Supposing, as I did and do, that Tavernier handled the Koh-i-Nur, I indicated the prison-palace of Shah Jahan as the repository of the Great Mogul. But, whichever diamond it may have been that the French traveller saw, the other was assuredly among those splendid stones that the old Emperor told the son who had usurped his throne that he would pound to dust if their surrender was insisted on. Anyone read in Indian history needs not to be told that the threat never had to be fulfilled; that Aurungzebe, content with the realities of power, cared little for the splendours that environed it, and left his captive father in the enjoyment of the allurements and the external pomp and vanity of a sovereign's surroundings, including the collection of jewels and precious stones in which his soul delighted. On his death they were brought to Aurungzebe by his sister Jehanira, who had shared her father's captivity.

It matters nothing to the subsequent history of the Koh-i-Nur whether it or the Great Mogul was the stone that remained in the custody of the fallen Emperor. But I have maintained that it was more probable that Shah Jahan should have retained the diamond that may be styled his private property, as having been given him by the Emir Jumla; and that therefore the stone seen in Aurungzebe's possession would in every probability have been the diamond of Babar, which, like the peacock throne and other gorgeous adornments of the presence chamber, would, as a Crown jewel, have remained in the imperial treasury.

Of course, this view of the matter involves great misgivings as regards Tavernier's accuracy. It involves his having applied to the only big diamond he saw the stories he had heard, from Bernier, no doubt, and from others, regarding that other great diamond given by the Emir Jumla to Shah Jahan. It further involves his having attempted to represent in a drawing a diamond he had seen several years before, but in a drawing so absolutely unlike the Koh-i-Nur as to be hardly recognizable as representing the Queen's diamond, and even less the diamond that he himself described, as he saw it, among the treasures of Aurungzebe.

The Great Mogul diamond had been cut by a European cutter. But, so far as it is of any value at all as evidence, Tavernier's drawing suggests a characteristically Indian-cut stone, much resembling in form and facetting the Russian diamond known as the "Orloff," which I have inspected, and can aver to be Indian in its cutting. The Koh-i-Nur, too, to which I personally gave careful attention in 1851, was no less unquestionably Indian in its facetting. Models in plaster-of-Paris made directly from the diamond confirm this; and traces of the original faces of the diamond, besides two large octahedral faces, appear to have been worked into the design of the facetting. The rows of facets were obviously put on so as to humour the original form of the stone and diminish its weight as little as possible; and notably they were thus skilfully arranged in regard to the upper edge of one of two large octahedral faces that has erroneously been described as a cleavage plane due to a fracture after the cutting had been performed. In fact, it and another large face, forming the base of the crystal, had not the lustre of cleavage surfaces, but wore the aspect of faces that had so far undergone attrition, probably in a river-bed, that the angle between them was no longer quite the true octahedral angle. The facets in general presented an imperfect adamantine lustre, and appeared slightly rounded, the result, probably, of the imperfect processes employed by the native Hindoo lapidary, especially in very early times.

Even Tavernier's drawing rudely indicates three rows of facets, put on in a manner that hardly consists with the fashion of a rose-cut diamond of European workmanship.

With my profound scepticism as to the critical value of Tavernier's arithmetic, I have ventured to think that the simplest explanation of all these instances of marvellous recurrence in various forms of the numbers representing the weight of the Koh-i-Nur is best explained by supposing that Akhil Khan gave Tavernier the traditional weight of the Babar diamond which he had placed in his hand, and that the French merchant translated this weight into carats, not as from the old ratis of Babar's or even of Akbar's day, but from the pearl ratis, of one or other value, with which he had become acquainted in the bazaars of India. Tavernier's rati, as calculated from the Paris carat on the ratio of ⅞, should have a value of 2·77088 troy grains, and as drawn from his various statements of equivalent weights it varies from 2·4066, in one case 2·750, to 2·797 troy grains. His mishkal also he puts at ⅙ the French ounce, *i.e.* 78·7 troy grains; which should, however, probably have been 6½ ounces to the mishkal, and the rati of Tavernier is entirely dissimilar to any known rati of ancient or modern India.

The 319½ ratis is readily explained on this hypothesis; and it is really too large a demand on our credulity to believe that two of the largest diamonds in the world should be severally of 319½ ratis and 320 ratis, though of different units of value, when a simpler explanation is able to dispose of the anomaly.

I have said that the marvellous coincidences of weight imported into the Koh-i-Nur history do not come to an end with Babar's 8 mishkals, with Anselm de Boot's 187½ carats, with Tavernier's 319½ ratis, nor even with Dr. Ball's miraculous chipping process, resulting in a reduction of the Great Mogul diamond to the identical weight of the Koh-i-Nur in 1850. The original diamond of Babar had to be accounted for, and its ghost had to be laid. So another coincidence had to be imported into the narrative, or rather into the romance. Another diamond had to be found, also with the precise weight of the Koh-i-Nur, and this Dr. Ball has ready to hand. The Darya-i-Nur, or "Sea of Light," reposes in the treasury of the Shah. Sir J. Malcolm saw it, and casually stated its weight as given to him at 186 carats. Now Sir J. Malcolm, during his residence at the Court of the Shah, not only was acquainted with the marvellous treasures in jewels brought by Nadir from the palace of Delhi, but he was enabled to have *facsimile* drawings of them made.

By the kindness of his son, General Malcolm, I possess the tracings of this dazzling wealth of jewellery. The Darya-i-Nur is a large flat diamond with bevelled edges, and in the form of a long rectangle. When Malcolm knew it, it was set in a glorious galaxy of mighty rubies. He could therefore have only known its weight from hearsay evidence, and the recorded carats were most likely the echo of those associated with the fame of the Koh-i-Nur. Now, I have no hesitation in asserting this Darya-i-Nur to be an old acquaintance of those familiar with Tavernier's pages. Unless two diamonds, flat, bevelled, and of identical dimensions, can be shown to co-exist, of above 200 carats weight, the stone known as the Golconda diamond or the Table diamond is no other than the Darya-i-Nur.

It happens fortunately to be one of the few stones described by Tavernier to the form and weight of which, as given by him, we can attach complete confidence. He had a lead model made from it in order to negotiate its sale: and he gives its weight as 176⅛ mangelins, or $242\frac{3}{16}$ "de nos carats." This gives its weight at 767·42 troy grains, or 240 English carats, this particular mangelin being, on Tavernier's estimate of 1⅜ of a carat, about 4·357 troy grains. Tavernier having had a lead model made of this remarkable flat diamond, he figures it no doubt with much exactitude. A copy of his figure and of the tracing of the Darya-i-Nur is subjoined, in which it will be seen that if the unsymmetrical end be cut off and the sides more accurately squared, so as to make the diamond a symmetrical rectangle, the figures of the two stones become identical in form and dimension. A card cut to represent the "Golconda" diamond, and the parts of it as described, gave the ratio of

the Golconda : the Darya-i-Nur = 10 : 8·5,

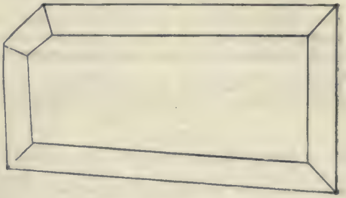
that is to say, the portion trimmed away was about 15 per cent.

The remaining stone would thus have a weight of about 214 English carats, and if 4 carats be allowed for the bevelling and squaring of the stone, the present weight of the Darya-i-Nur should be about 210 English carats.

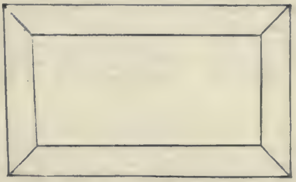
I trust I have thus laid this last phantom raised by the author of the "true history." But the final problem as to the Great Mogul diamond still remains.

If the Queen's proud trophy of the final conquest of India is indeed the great Koh-i-Nur, the old Malwa diamond descending to Her Majesty from the possession of Patan and Mogul dynasties of Delhi; carried off to Persia and named by Nadir; seized as the potent talisman of empire by Ahmed Shah, and held by his Durani descendants till it came back to India, the companion of the exile of Shah Sujah, and then torn from him by the grim Lion of Lahore—true to its destiny as "the possession, ever, of him that was the strongest,"—if this be indeed the stone that, from early times to 1850, preserved its form and weight of 8 mishkals, where was, and where is now, the Great Mogul diamond that Bernier told of? The answer is, I believe, the simplest and the most natural: It is, where the historian would look for it, in the treasury of Teheran. One large diamond, standing high upon an elliptic base, is there, or was there, in Sir John Malcolm's day. Its long diameter is much larger, and its shorter diameter smaller, than that of the diamond figured by Tavernier.

I do not assert it to be the Great Mogul. I assert merely that it probably is that great diamond; and I hope that in what has been said in the criticisms I have here offered upon the writers on the Koh-i-Nur I have averred nothing that does not rest on proof; that I have offered no conjecture that is not supported by reasonable probability; and that I have made no assault on any theory or fact asserted to be such by others, without at least offering some justification for my criticism in the reasons and facts I have been able to adduce.



Golconda Table Diamond.



Darya i-Nur.

A true history of the Koh-i-Nur has still to be written. I hope I have, in these criticisms, done something to clear the way for the writer of it. Other avocations and duties may prevent my undertaking the interesting task. At any rate, if it should ever be mine to perform it, I trust the result will at least bear some verisimilitude to a true history.

N. STORY-MASKELYNE.

SCIENTIFIC SERIALS.

A LARGE portion of the number of the *Botanical Gazette* for July is occupied by an instalment of Mr. John Donnell Smith's "Undescribed Plants from Guatemala"; several of the new species are figured. New parasitic or saprophytic Fungi—Hyphomycetes and Uredineæ—are described in this number by Mr. R. Thaxter, and in that for August by Mr. J. C. Arthur. In the latter, M . T. Holm continues his study of some anatomical characters of North American Gramineæ, and Mr. F. Lamson Scribner contributes a sketch of the flora of Orono, Maine.

THE numbers of the *Journal of Botany* for August and September contain the conclusion of Mr. G. Murray's important paper on the Algæ of the Clyde sea-area, accompanied by a map showing the various depths. This paper has now been issued separately. In his notes on Mycetozoa, Mr. A. Lister describes species found in various herbaria not included in Dr. Cooke's "Myxomycetes of Great Britain"—three of them new

The paper is illustrated by five plates. Three new British species of *Hieracium* are described by Mr. E. F. Linton and Mr. W. H. Beeby.

SOCIETIES AND ACADEMIES.

SYDNEY.

Royal Society of New South Wales, August 5.—H. C. Russell, F.R.S., President, in the chair.—On the microscopic structure of Australian rocks, by Rev. J. Milne Curran.—The Chairman presented the Society's bronze medal and a money prize of £25, which had been awarded to Father Curran for this paper.—Prof. Anderson Stuart exhibited his new instrument for demonstrating the nature of such waves as those of light.

August 10.—H. O. Walker, in the chair.—Notes on slicing rocks for microscopic study, by Rev. J. Milne Curran, illustrated by rock sections in various stages of preparation for mounting.

August 12.—C. W. Darley, in the chair.—Methods of determining the stresses in braced structures, by J. I. Haycroft.

PARIS.

Academy of Sciences, September 28.—M. Duchartre in the chair.—Notice of the works of M. P. P. Boileau, by M. Maurice Lévy.—Remarks on the international prototype of the metre, by M. Foerster.—Observations of four asteroids, discovered at Nice Observatory on August 28 and September 1, 8, and 11, by M. Charlois. The positions on the dates of discovery are given.—Verification of the law of refraction of equipotential surfaces, and measurement of the dielectric constant, by M. A. Perot.—Relation between the index of refraction of a body, its density, molecular weight, and diathermancy, by M. Aymonnet.—On the cyclone of August 18, at Martinique, by M. G. Tissandier.

BRUSSELS.

Academy of Sciences, August 1.—M. Plateau in the chair.—On the predominance and extension of Upper Eocene deposits in the region between the Senne and the Dyle, by M. Michel Mourlon.—Direct synthesis of primary alcohols, by Dr. P. Henry.—On circular sections in surfaces of the second degree, by Prof. Cl. Servais.—On the curvature of lines of the order p possessing a multiple point of the order $p - 1$, by M. A. Demoulin.—Preliminary notes on the organization and development of different forms of Anthrozoaires, by M. Paul Cerfontaine. The author describes a new Cerianthus from the Red Sea, and names it *Cerianthus brachysoma*. He has also studied in detail the tentacles of *Cerianthus membranaceus*, and the variations of these organs during successive stages of individual evolution, and relates an interesting case of regeneration observed in *Astrodes calycularis*.—Researches on the lower organisms, by M. Jean Massart.

GÖTTINGEN.

Royal Scientific Society.—The *Nachrichten* from June to August 1891 contain the following papers of scientific interest:—

June.—Karl Heun, Berlin, mathematical note on the integration of the equation for the motion of Gauss's bifilar pendulum.

July.—Fr. Schilling, note on an interpretation of the formulæ of spherical trigonometry when complex values are assigned to the sides and angles of a spherical triangle.

August.—Eduard Riecke, on the molecular theory of piezo-electricity and pyroelectricity.—Tammann and W. Nernst, on the maximum vapour tension of hydrogen liberated from solutions by metals.—Tammann, the permeability of precipitate-films.—Eduard Riecke, on a surface connected with the electrical peculiarities of tourmaline.—David Hilbert, the theory of algebraic invariants of forms with any number of variables.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

The Universal Atlas, Part 7 (Cassell).—Food, Physiology, &c.: W. Durham (Black).—British Edible Fungi: Dr. M. C. Cooke (Paul).—South Africa, from Arab Domination to British Rule: edited by R. W. PHYSICAL CHEMISTRY.

Outlines of General Chemistry. By Wilhelm Ostwald. Translated with the Author's sanction by James Walker, D.Sc., Ph.D. Pp. 396. (London: Macmillan and Co, 1890.)

THAT much may be gained by a judicious use of the methods of the physicist in elucidating chemical phenomena most chemists will admit; and, considering the rapid strides made of late years in physical chemistry, it seems surprising that so little has been done to give a connected account, suited to the wants of the student, of the main researches in this important field of investigation. Original communications on physical chemistry are on the increase. The chemist has now, in the *Zeitschrift für physikalische Chemie*, a periodical devoted exclusively to this branch of his science, and during the four years or so of the existence of this journal, its success has testified amply to the want which it supplies.

Ready access to original memoirs is not, however, the boon of the ordinary student; and, even if it were otherwise, the want of some scheme whereby to systematize his reading and classify his information, much of which is still open to wide difference of opinion, would almost invariably lead to confusion.

The majority of the text-books make little or no attempt at supplying this want. Occasionally a few of the larger chemical treatises spare a few pages to "physical methods," and such text-books as Meyer's "Modernen Theorien" or Muir's "Principles of Chemistry" contain much of the matter classed under physical chemistry.

Yet a comprehensive idea of what has been done in tracing relationships between physical properties and chemical composition and in utilizing physical measurements in investigating chemical change, cannot be obtained from most text-books. Indeed, so far as we know, only one is designed to serve this purpose, and that is the "Lehrbuch der Allgemeinen Chemie" of Prof. Ostwald. "Allgemeinen" rather than "Physikalische" "Chemie" has been used as a title for the work; but in the main it deals with physical chemistry. The book under notice seems to be an English translation of an abstract of the "Lehrbuch"; and, were it for no other reason than that it furnishes a well-conceived syllabus of the subject-matter of general and physical chemistry, it would be worthy of careful consideration.

The book is divided into two parts—Part I. chemical laws of mass; Part II. chemical laws of energy.

The first part opens with stoïchiometry. The laws of chemical combination, the determination of atomic weights, and a useful summary of the atomic weight estimations of the different elements are here given. Then follow sections treating of such of the physical properties of gases, of liquids, of solutions, and of solids as the chemist must be familiar with, and of the more important relations which have been established between such physical properties and chemical composition.

The section dealing with solutions is noteworthy as containing the first fairly complete statement, in an English text-book, of the facts grouped around the physical theory of solution which has arisen out of a knowledge of osmotic pressure. Part I. closes with chapters on chemical systematics—the choice of atomic weights, the periodic law, the development of the present conception of molecular structure.

In the earlier portions of the second part, thermochemistry, photo-chemistry, and electro-chemistry are discussed. The last takes up the constitution of electrolytes, electric conductivity, and the Arrhenius dissociation hypothesis.

Chemical dynamics and chemical affinity are treated in the last two sections, and afford many illustrations of the use of physical methods in the study of chemical change. In the case of acids competing for the same base are found instances where physical methods alone are available to estimate the nature and extent of the chemical action. In these sections, the exposition of the law of mass action, and of the velocity of chemical change, is especially clear. Owing to recent work on the subject, the discussion of affinity is here more complete than in the "Lehrbuch," and however unsatisfactory the notion of fixing specific affinity constants be considered, the account set out is the most systematic and plausible yet published.

There is no doubt that the general conception of the book is admirable; it contains much that is new; to the advanced reader it will be refreshing after the time-honoured methods of the ordinary text-books. Yet the general impression which we think will be formed on looking through it, is that the attempt made to compress information into too small a compass has detracted much from its value.

A certain amount of detail is always necessary to intelligent comprehension, and in many parts of the book there is too much bald statement to satisfy the reader who approaches the subject for the first time. Mainly for this reason it is a question whether the work will answer the expectation of the author that it will "meet the requirements of the student who, while not intending to devote himself to the detailed study of general chemistry, still wishes to follow *intelligently* the progress recently made in this important branch of science."

The time which has been spent in preparing the chapters on several important topics seems to have been inadequate. For instance, the molecular volumes of liquids are disposed of in little more than three pages. Kopp's laws are quoted, although not one of them can now be taken as valid; Schiff's inaccurate rule as to the volumes of isomers also finds a place. Instead of apparently settling the question by stating "molecular volumes to be additive magnitudes subject to constitutive influence," little more space would have been occupied in showing how, in different groups of isomers, the volume varies with the constitution. If recent progress on the subject was to be made use of, the facts that the effects of molecular weight and constitution cannot be disentangled, that even from the comparison of compounds of similar constitution, definite atomic volumes, determined for the boiling-point, cannot be obtained—that, in short, atomic volumes cannot be regarded as physical constants—ought surely to have been emphasized.

The desire to economize space is probably the cause of several examples of rather mixed information. The following paragraph occurs on p. 104:—

> "Ordinary dextrotartaric acid, for instance, has precisely the *same properties* as lævotartaric acid; but the compound of both which crystallizes from their mixed solutions on evaporation—racemic acid—has quite a different character. The first-named crystallize anhydrous, the last hydrated. The simple acids do not precipitate a solution of calcium sulphate. The compound acid does, and so forth. Yet it should be emphasized that such *differences* only occur with *solid* compounds; racemic acid behaves in *solution like a mixture* of the two components."

Seeing that this book is one of the very few in which Van der Waals's work obtains the prominence which it deserves, and which has been long delayed, it seems a pity that pains have not been taken to make the account accurate.

On p. 67 the reader is led to infer that b in Van der Waals's equation is the volume of the molecules; the true value of b is four times the volume of the molecules. Again, on p. 90, it is stated that the equation "is deduced only for the case where the volume of the substance is eight times as large as the magnitude b"; correctly given, this should be, "is deduced for cases where the volume is greater than $2b$."[1]

Admirable as may be the exposition of the theory of solution from the advanced standpoint here taken up, it may rightly be questioned whether the student is fairly treated. The physical theory of solution, the dissociation hypothesis, no one knows better than the author, are still strongly contested: should the student therefore not have heard a little more of the other side of the question? Particularly objectionable is the application of such terms as Boyle's law, Gay Lussac's law, &c., to solutions. In the opening chapters of the book the reader is familiarized with the kinetic theory of gases; he is enabled to form a mental picture of the mechanism which results in the pressure of a gas. How he, or, indeed, anyone, can form a similar picture for a solution, when the molecules of the solvent have also to be taken into consideration, it is difficult to imagine. By using for solutions a term such as Boyle's law, which for gases is capable of a perfectly definite interpretation, the real difficulty of the question is ignored, and misconception is almost sure to arise, especially in the case of the beginner.

We noticed in passing that, on p. 364, polybasic is used for dibasic; on p. 370, $k_1a = k'_2h^2a$ should be $k_1a = k'_1h^2a$. Frequently there is no distinction between the type of letters occurring in formulæ, and that in which the book is printed. Reference in the body of the book to portions of formulæ is therefore apt to lead to confusion, and in any case lacks clearness, as may be seen on pp. 297 and 369.

The work, from its very title, apart even from the reputation of the author, will no doubt appeal to a large class of readers; as an English text-book of chemistry it is unique. We venture to think, however, that if such points as those indicated were attended to, particularly the question of space, its sphere of usefulness would be materially enlarged.

UNITED STATES FISH COMMISSION REPORTS.

Bulletin of the United States Fish Commission. Vol. VIII. for 1888. (Washington, 1890.)

IN 1881 the Senate and House of Representatives of the United States of America authorized the public printer to print from time to time any matter furnished to him by the United States Commissioner of Fish and Fisheries relative to new observations, discoveries, and applications connected with fish culture and the fisheries. The printed matter was to be capable of being distributed in parts, the whole was to form an annual volume or Bulletin not exceeding 500 pages, and the edition was to be limited to 5000 copies.

Seven volumes of this important series have since been published, and have been noticed in our pages. They were composed chiefly of translations or republications of articles on fish or fisheries which had appeared in European periodicals or as State documents; extracts from the official correspondence, with statistics of work done; and often of short articles of direct scientific interest on American fish; the whole forming a most valuable, practical encyclopædia of everything relating to the economic study of fish.

An eighth volume, dated 1890, but being the Bulletin for 1888, has just been issued from the Washington Press. The increased operations of the United States Fish Commission during 1888 have made it possible to devote almost the whole of this volume to the results of the work of the Commission, and it will be found to contain matter of considerable interest. The size of the volume has been slightly enlarged, so as to afford room for larger illustrations.

Of the twelve memoirs or papers contained in this volume, five relate to local collections of fishes. Mr. Tarleton H. Bean gives notes on a collection made at Cozumel, Yucatan: sixty species are enumerated; two new species are described and figured. Mr. C. H. Bollman reports on the fishes of Kalamazoo, Calhoun, and Antrim counties in Michigan. Mr. S. A. Forbes contributes a preliminary account of the invertebrate animals inhabiting Lakes Geneva and Mendota, in Wisconsin, and gives some particulars of the fish epidemic in the latter lake in 1884. Mr. C. H. Gilbert describes some fish from the lowlands of Georgia. Mr. D. S. Jordan gives a report of explorations made during 1888 in the Alleghany region of Virginia, North Carolina, and Tennessee, and in Western Indiana, with an account of the fishes found in each of the river-basins of those regions.

In a review of the genera and species of Serranidæ, by D. S. Jordan and C. H. Eigenmann, we have an enumeration of all the genera and species belonging to this family found in the waters of America and Europe, together with the synonymy of each, and analytical keys by which the different groups may be distinguished. One hundred and nineteen species are admitted, and thirty-four genera. This memoir is illustrated with ten plates. Mr. J. W. Collins contributes a paper on improved types of vessels for use in the market fisheries, with some notes on British fishing-steamers; and Mr. W. F. Page gives an account of the most recent methods of hatching fish-eggs. Mr. T. H. Bean reports favourably on the feasibility of introducing the mountain mullets of Jamaica (Agonostoma) into some of the Alpine streams of the Southern States; and Mr. R. Rathbun gives a detailed report on the introduction of lobsters to the Pacific shores of the United States.

The two most important contributions to this volume are, however, those by Lieutenant Tanner, "On the Result of the Explorations of the Fishing-grounds of Alaska, Washington Territory, and Oregon during 1888," and by Mr. John A. Ryder, "On the Sturgeons and Sturgeon Industries of the Eastern Coast of the United States."

Although it had been known for many years that the Pacific coasts of North America were abundantly provided with edible fishes, it was not until 1880 that the exact species of these were correctly determined; the Alaskan cod proving to be the same species as that of the North Atlantic. The absence of large and convenient markets hindered the development of the Pacific coast fisheries; but, with the completion of the railroad system, this state of things has changed, and a strong interest is now being shown in all that relates to the development of the fish industry. This Report affords us the first accurate information that has been obtained respecting most of the fishing-grounds in Alaska. The five banks whose positions were indicated by older surveys—namely, Davidson, Sannakh, Shumagin, Albatross, and Portlock banks—were more thoroughly examined than were the intervening areas, some of which, however, may, upon further examination, prove to contain fishing-banks of equal value, and not inferior in size, to at least the smaller of the banks mentioned.

Good fishing was obtained at nearly all localities where trials were made with hand-lines, whether upon defined banks or upon the more level grounds between them, and it seems natural to infer that the entire submerged plateau from off Unalashka Island to Fairweather Ground is one immense fishing-bank, limited upon the outer side only by the abrupt slope, which may be said to begin about the 100-fathom curve.

Although the great bulk of this Report relates to the fishing-banks and fishes, yet we get various glimpses of many interesting facts relating to other of the vertebrate and to many of the invertebrate forms met with. Off Popoff Island, large masses of sea-urchins, star-fishes, and large Medusæ were found in the seine nets, and the hooks became entangled with fine specimens of sea-pens (Pennatula). At the Lighthouse Rocks a landing was made, to examine a large rookery of Steller's sea-lion (*Eumetopias stelleri*). Several hundreds of these animals were found crowded together upon a very limited area. As the party landed, the old sea-lions came tumbling down over the rocks in great eagerness to reach the sea; a few, whose retreat was intercepted, were seen to jump from their high positions directly into the water, apparently sustaining no injury from the plunge, although the distance was considerable, especially for such large animals. A couple of killer whales (Orca), attracted by the disturbance and the sight of so many seals in the water, came quite close to the rocks, causing the seals to gather nearer the shore, and to cast frightened looks of alarm towards the whales, whose dorsal fins showed not less than four feet above the surface of the water. These rocks were entirely destitute of vegetation. Off Trinity Islands, large quantities of crustaceans, worms, mollusks, echinoderms, and sponges were taken—an especial feature of the haul consisting of over a hundred specimens of a fine large free crinoid. As all these specimens will find their way to the United States National Museum, we may expect soon to have recorded many additions to the marine fauna of the North Pacific.

Mr. John A. Ryder's paper will also be perused with great interest. Having undertaken to report on the sturgeons and sturgeon fisheries of the eastern rivers of the United States, he repaired in May 1888 to Delaware City, which is described as a very important centre of the sturgeon fishery. Two species of the genus Acipenser are to be found in the waters along the Atlantic coast of the United States; these are *A. sturio*, L., and *A. brevirostris*, Le Sueur. The former (the common sturgeon) is the only one of any commercial importance at Delaware, as Le Sueur's species is so rare that only five specimens of it were taken by Mr. Ryder; and since the date of its first being described, in 1817, it does not appear to have been until now again recognized. Of the other American species, one is the very distinct fresh-water sturgeon of the Lake region, and two others are to be found on the Pacific coast.

The embryological data of this memoir have been in a good measure drawn from the author's original investigations, but he has fortunately also given us in addition details from the writings of Balfour, Knoch, Parker, Zograff, and Salensky. He found it perfectly practicable to fertilize artificially the sturgeon's roe, and thinks it possible that millions of young sturgeon might be developed in this way. He treats in detail of the dermal armature of the sturgeon's body, illustrating this part of his subject by numerous photogravures, describes the organs of locomotion, the lateral line system, the viscera, and lymphatics. The sources of the food of this fish and its peculiar habits are next considered, and special information is given about the preparing of the flesh for market, and the manufacture of the caviare. A very useful bibliography of the literature relating to the sturgeon is appended. This memoir is illustrated by twenty-two plates.

THE CATALOGUE OF THE WASHINGTON MEDICAL LIBRARY.

Index Catalogue of the Library of the Surgeon-General's Office, U.S. Army. Vol. XI. Phædronus—Régent. Pp. 1102. (Washington, 1890.)

THE appearance of these very fine folios year by year for the last eleven years is a very good proof to all lovers of books and collections of books in Europe that they have some sympathetic friends in America who have the will and the power to make one at least of their finest libraries well known throughout the world. Its title as the Library of the Surgeon-General's Office may once have sounded like the name of a collection of musty Blue books tied together with red tape; but, thanks to the energy of its Librarian, Mr. J. S. Billings, which we feel constantly in the monthly publication of the *Index Medicus*, everyone knows now that it is nothing of the kind, but one of the first medical libraries, if not the first, in the world, containing much more medical literature than is to be found in the libraries of the richer English corporations, the Royal Colleges of Physicians and Surgeons, or of the more learned and active Societies, such as the Royal Medical and Chirurgical Society, or, indeed, in the British Museum or Bibliothèque Nationale. And though the Washington Library is of comparatively recent date, going back only some thirty years, yet it contains a very fine collection of books both of the fifteenth and sixteenth centuries; and at the same time the great difficulty of the maker of a catalogue to a modern library, viz. the immense mass of the newspaper and periodical literature of to-day, has been fairly faced and overcome. During the past year, 287 periodicals have been added to the list of those that are taken in, raising the total number to about 7500, of which at least 3900 are current. The vast aggregate of articles in these are duly catalogued, each under the head of its subject-matter. It is not surprising, therefore, that we should find 80 of these large square folio pages filled in the present volume with entries under the heading Phthisis, 78 under Puerperal Diseases, 67 under Pregnancy, and 56 under Pneumonia. Even as devoted entirely to a lesser matter like the pulse, there are catalogued 150 volumes and 350 articles in periodicals. The care with which the records of the smallest steps in the past history of medicine have been preserved is shown by the accumulation of twenty-five editions of the "Pharmacopœia" of the Royal College of Physicians of London from the years 1657 to 1851. Under such headings as Psychology, we may see the wide range also of the larger subjects embraced in the Library, for the collection under this heading begins with many expositions of Aristotle, and does not neglect Plato, but takes in also the recent books of modern authors, such as the last edition of Herbert Spencer's "Principles of Psychology" and Taine's "De l'Intelligence." The eleventh volume of this magnificent catalogue brings us to within measurable distance of the end; from the analogy of lesser works, in fact, it seems probable it may be completed in three or at most four volumes, and it will then be a great monument among modern catalogues, and in its articles under subject titles form a most valuable dictionary to all who are seeking a clue to the complete historical study of medicine and surgery.

A. T. Myers.

OUR BOOK SHELF.

Dictionary of Political Economy. Edited by R. H. Inglis Palgrave, F.R.S. Part I. Abatement—Bede. (London: Macmillan and Co., 1891.)

This is a first instalment of what promises to be a very valuable addition to the English library of political economy. The plan of the work is laid down on broad lines, and includes not only articles dealing with strictly economic subjects, and explanations of legal and business terms, but good (though necessarily brief) accounts of historical events bearing on economic history, such as the establishment and downfall of the *ateliers nationaux* in Paris in 1848, and biographical notices of deceased writers whose life and work has had any connection with the development of economic theory or practice. That the biographical section of the dictionary is conceived in a liberal spirit is sufficiently proved by the fact that the first part, now under review, includes notices of Addison and Thomas Aquinas; the claim of the former to a place in a dictionary of political economy is based in the main on the fact that he held an official position in the Government of his time as one of the Lords Commissioners of Trade. This rather remote connection with economics may be open to criticism; and it remains to be seen whether Mr. Palgrave will include in his dictionary the honoured names of William Wordsworth and Robert Burns. It is not, however, desirable to say anything in the way of criticism which should tend to narrow the scope of the work. Its interest and vitality depend, to a large degree, on its broad inclusiveness.

The biographical articles are particularly well done, and we would single out that on the late Mr. Bagehot for special commendation. It gives not only the dry facts of his career, but presents a living picture of a peculiarly fascinating personality, and also a very just estimate of his place in, and services to, economic literature. Among the most important articles in the present instalment of the dictionary may be mentioned that on agricultural communities, by Prof. J. S. Nicholson, and that on banks. The former gives an admirable summary of the conditions of life in existing village communities in Russia and India, and also a digest of the results arrived at by the researches of Sir Henry Maine, Mr. Seebohm, and M. de Laveleye, as to the existence of various forms of village communities in the remote past in our own and other countries. The article on banks gives an historical sketch of the development of banking in various countries, contributed by different writers, each with special knowledge of his own portion of the subject. Thus we have brought together within the compass of a few pages an account of the land banks and the Schulze Delitsch credit banks of Germany, the savings banks (trustee and Post-office) of England, and the popular banks of Italy.

The names of the contributors to the present volume, and also those who have promised their assistance in the preparation of the rest of the work, are a guarantee of its high value to all students of social and economical subjects.

South Africa, from Arab Domination to British Rule. Edited by R. W. Murray, F.R.G.S. With Maps, &c. (London: Edward Stanford, 1891.)

One of the objects of this book is to bring out the contrast between Portuguese rule in South Africa and the influence exerted by England. The contrast is certainly striking enough; and it is shown most clearly, as in the present work, by a simple statement of historic facts. In the first chapter, Prof. Keane sketches the career of the Portuguese in the various South African regions they have dominated. This is followed by translations from the "Africa" of Dapper, a Dutch writer of the seventeenth century, showing that at that time the Portuguese stationed on the African coasts made no effort to acquire extensive knowledge of the interior. The editor then records the main facts relating to the Dutch and English settlements in the south, and the recent movements northward to Bechuanaland, Matabeleland, and Mashonaland. Mr. J. W. Ellerton Fry, late of the Royal Observatory, Cape Town, Lieutenant of the British South African Company's expeditionary force, gives an account of what he himself observed during the march into Mashonaland in 1890; and much information with regard to the east coast of Africa at Beira, Pungwe, and the Zambesi is presented in notes from the diary and correspondence of Mr. Neville H. Davis, late surveyor and hydrographer to the Queensland Government, who, in 1890, accompanied an expedition sent to East Africa to discover whether there was any mineral or other wealth in concessions granted by the Mozambique Company. The book has not been very systematically planned; but it brings together so many facts which are not readily accessible elsewhere, that it cannot fail to interest readers whose attention is for any reason especially directed to South Africa. It includes several excellent maps, and two engravings of Cape Town, showing Cape Town as it was in 1668, and as it is in 1891.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Pink Marine Micro-organism.

WHILE dredging lately in Loch Fyne, I noticed through the clear water, in a little shallow bay on the north side of the entrance to East Loch Tarbert, a number of pink patches on the sand. These could just be reached by wading from a boat at the lowest tides, and were then found to be roughly circular spots, about a foot in diameter, where the clean white sand was discoloured, most of the surface grains being almost exactly the tint of ordinary pink blotting-paper.

Under a low power of the microscope, it is seen that the pink particles are ordinary clear quartz sand-grains, incrusted with little bright pink jelly masses, generally of elongated or sausage-like forms, and averaging 0·1 mm. in length. Further magnification shows that each jelly mass is crowded with minute very short rods, or ellipsoids, of about 0·0015 mm. in length, and about half as much in breadth.

This appears to be a micro-organism in the zooglœa condition, and I do not know that any such pink marine form, living on clean sand, in *pure* sea water, has been noticed. It may possibly be one of the forms of *Beggiatoa rosea-persicina*, but it does not agree satisfactorily with any of the descriptions I have access to here. I have still some of the material alive in sea water, and shall be glad to hand it over to any biologist who is now working specially at such forms, and would like to investigate this one.

Advertisements for Instructors.

THE friends of technical education can no longer complain that the subject is not receiving attention. The numerous advertisements for instructors of all sorts, from County Councils and other bodies, colleges and schools are full evidence that much is being attempted.

Whether all the plans and proposals and experiments will lead to the hoped-for results only time will show. Some of us have our doubts as regards many of them.

Meantime, one of the advertisements deserves a passing notice. A well-known technical school is in search of "a demonstrator in the Metallurgical Department to take the lectures in geology and mineralogy, and to give instruction in dry assaying and in iron and steel analysis" (see NATURE of this week).

This is certainly a large and considerably mixed "order," calculated to make thoughtful people wonder what sort of instruction is expected to be given by this gifted person (who is to have the princely sum of £100 per annum); and whether, if the "metallurgical demonstrator" is to throw in geology and mineralogy as a sort of extra to his own special work, the other demonstrators and professors are expected to be equally widely qualified; let us say a chemical demonstrator to give lectures on mechanical engineering and ship-building?

Newcastle-on-Tyne, October 10. M.

"Rain-making."

I THINK the following will be of interest to your readers in connection with the "rain-making" experiments in Texas. On October 1, at 5 p.m., five tons of gunpowder was exploded in a single blast at the Penrhyn slate quarries in order to clear away a very large mass of useless rock. A strong wind had been blowing all day, and the clouds, though heavy, were high; there had been no rain, and not much sunshine, and the temperature was somewhat low.

Immediately after the explosion the wind fell to a dead calm, which lasted about 5 or 6 minutes, and 20 minutes later a fine rain began to fall, which soon became heavy and continued for an hour and a half. By 7 p.m. all disturbances produced by the explosion had apparently passed away, and the weather was again similar to what it had been during the day. The rainfall was entirely local, there being none, as far as I could learn, outside a radius of 6 or 7 miles from the quarry.

W. R. PIDGEON.

Alum Solution.

WITH reference to the question raised by Mr. H. N. Draper in NATURE, vol. xliv. p. 446, as to the practical superiority of an alum solution over simple water in absorbing such radiations as are chiefly instrumental in producing heat, I may recall some experiments made by myself five years ago (Brit. Assoc. Report, 1886, p. 309). The source of radiation employed was a paraffin lamp with a glass chimney, the various solutions were contained in a glass cell with parallel sides, and the "radiometer" was a delicate thermopile, the face of which was blackened with camphor smoke. The following results, among others, were obtained:—

Solutions, &c.	Diathermancy.
Empty cell	1000
Water distilled	197
Water from tap	200
Alum, saturated solution	204

It is clear therefore that, at least under conditions like those of my experiment, plain water will answer the purpose of an absorbent rather better than an alum solution. Possibly the "alum cell" tradition rests upon no better foundation than many others, which are generally accepted simply because it does not occur to people to question them.

SHELFORD BIDWELL.

October 10.

B.Sc. Exam. Lond. Univ. 1892.

THERE are, I believe, in London at the present time a number of men desirous of offering geology as one of three subjects required at the Degree Examination in Science, but who are deterred from so doing by the fact that it is impossible to obtain adequate evening class tuition in this subject.

Enquiries at the various teaching institutions have failed to discover a single opportunity for working up to the required standard in both theoretical and practical branches.

I have therefore laid the matter before Prof. Wiltshire, of King's College, Strand, with the result that he has very kindly consented, in the event of enough men requiring it, to supplement his lectures on geology and mineralogy by a course of instruction in petrology, embracing the study of hand specimens and microscopical examination of rock sections.

By giving publicity to the matter, it is hoped that a sufficient number of B.Sc. candidates will be forthcoming to ensure the establishment of this class.

The time-table for the complete course will be as follows:—

Monday	Petrology ...	6–7 p.m.
	Mineralogy ...	7–8 ,,
	Geology ...	8–9 ,,

The lectures and practical work, together with the summer field excursions, under the direction of Prof. Wiltshire, will prove a great boon to such as are prevented from attending day courses, and will undoubtedly secure admirable preparation for the examination specified.

I shall be glad to hear from anyone interested in the matter, so that arrangements may at once be made for the first sitting to take place on Monday, October 19.

EDWARD J. BURRELL.

Some Notes.

THOSE who have visited Venice in spring know how rampant mosquitoes become after the flight of the swallows, which have kept them in check, for the north—usually in May.

A word for the sparrows—which have been very active in the gardens hereabouts this season, preying on the green flies and larvæ infesting the creepers and ferns in particular; but very few starlings have been observed, to the great increase of earthworms in the lawns. The crane-fly, which usually swarms in the fields of the Mansfield estate in September, has been very rare, too, this season. The dragon-fly visited us this summer for the first time.

Apropos to the records of the "rare phenomenon," such a summer aurora was observed at Rothbury, Northumberland, in the latter half of August 1880.

To conclude this farrago of notes: for "*non* pas travaillés" in Mr. Sclater's quotation of the Prince of Canino's words (xliv. p. 518), read "*n'ont* . . ." J. J. WALKER.

Hampstead, N.W., October 3.

THE MOLECULAR PROCESS IN MAGNETIC INDUCTION.[1]

MAGNETIC induction is the name given by Faraday to the act of becoming magnetized, which certain substances perform when they are placed in a magnetic field. A magnetic field is the region near a magnet, or near a conductor conveying an electric current. Throughout such a region there is what is called magnetic force, and when certain substances are placed in the magnetic field the magnetic force causes them to become magnetized by magnetic induction. An effective way of producing a magnetic field is to wind a conducting wire into a coil, and pass a current through the wire. Within the coil we have a region of comparatively strong magnetic force, and when a piece of iron is placed there it may be strongly magnetized. Not all substances possess this property. Put a piece of wood or stone or copper or silver into the field, and nothing noteworthy happens; but put a piece of iron or nickel or cobalt and at once you find that the piece has become a magnet. These three metals, with some of their alloys and compounds, stand out from all other substances in this respect. Not only are they capable of magnetic induction—of becoming magnets while exposed to the action of the magnetic field—but when withdrawn from the field they are found to retain a part of the magnetism they acquired. They all show this property of retentiveness, more or less. In some of them this residual magnetism is feebly held, and may be shaken out or otherwise removed without difficulty. In others, notably in some steels, it is very persistent, and the fact is taken advantage of in the manufacture of permanent magnets, which are simply bars of steel, of proper quality, which have been subjected to the action of a strong magnetic field. Of all substances, soft iron is the most susceptible to the action of the field. It can also, under favourable conditions, retain, when taken out of the field, a very large fraction of the magnetism that has been induced—more than nine-tenths—more, indeed, than is retained by steel; but its hold of this residual magnetism is not firm, and for that reason it will not serve as a material for permanent magnets. My purpose to-night is to give some account of the molecular process through which we may conceive magnetic induction to take place, and of the structure which makes residual magnetism possible.

When a piece of iron or nickel or cobalt is magnetized by induction, the magnetic state permeates the whole piece. It is not a superficial change of state. Break the piece into as many fragments as you please, and you will find that every one of these is a magnet. In seeking an explanation of magnetic quality we must penetrate the innermost framework of the substance—we must go to the molecules.

Now, in a molecular theory of magnetism there are two possible beginnings. We might suppose, with Poisson, that each molecule becomes magnetized when the field begins to act. Or we may adopt the theory of Weber, which says that the molecules of iron are always magnets, and that what the field does is to turn them so that they face more or less one way. According to this view, a virgin piece of iron shows no magnetic polarity, not because its molecules are not magnets, but because they lie so thoroughly higgledy-piggledy as regards direction that no greater number point one way than another. But when the magnetic force of the field begins to act, the molecules turn in response to it, and so a preponderating number come to face in the direction in which the magnetic force is applied, the result of which is that the piece as a whole shows magnetic polarity. All the facts go to confirm Weber's view. One fact in particular I may mention at once—it is almost conclusive in itself. When the molecular magnets are all turned to face one way, the piece has clearly received as much magnetization as it is capable of. Accordingly, if Weber's theory be true, we must expect to find that in a very strong magnetic field a piece of iron or other magnetizable metal becomes *saturated*, so that it cannot take up any more magnetism, however much the field be strengthened. This is just what happens: experiments were published a few years ago which put the fact of saturation beyond a doubt, and gave values of the limit to which the intensity of magnetization may be forced.

When a piece of iron is put in a magnetic field, we do not find that it becomes saturated unless the field is exceedingly strong. A weak field induces but little magnetism; and if the field be strengthened, more and more magnetism is acquired. This shows that the molecules do not turn with perfect readiness in response to the deflecting magnetic force of the field. Their turning is in some way resisted, and this resistance is overcome as the field is strengthened, so that the magnetism of the piece increases step by step. What is the directing force which prevents the molecules from at once yielding to the deflecting influence of the field, and to what is that force due? And again, how comes it that after they have been deflected they return partially, but by no means wholly, to their original places when the field ceases to act?

I think these questions receive a complete and satisfactory answer when we take account of the forces which the molecules necessarily exert on one another in consequence of the fact that they are magnets. We shall study the matter by examining the behaviour of groups of little magnets, pivoted like compass needles, so that each is free to turn except for the constraint which each one suffers on account of the presence of its neighbours.

But first let us see more particularly what happens when a piece of iron or steel or nickel or cobalt is magnetized by means of a field the strength of which is gradually augmented from nothing. We may make the experiment by placing a piece of iron in a coil, and making a current flow in the coil with gradually increased strength, noting at each stage the relation of the induced magnetism to the strength of the field. This relation is observed to be by no means a simple one: it may be represented by a curve (Fig. 1), and an inspection of the curve will show that the process is divisible, broadly, into three tolerably distinct stages. In the first stage (*a*) the magnetism is being acquired but slowly: the molecules, if we accept Weber's theory, are not responding readily—they are rather hard to turn. In the second stage (*b*) their resistance to turning has to a great extent broken down, and the piece is gaining magnetism fast. In the third stage (*c*) the rate of increment of magnetism falls off: we are there approaching the condition of saturation, though the process is still a good way from being completed.

Further, if we stop at any point of the process, such as P, and gradually reduce the current in the coil until there is no current, and therefore no magnetic field, we shall get a curve like the dotted line PQ, the height of Q showing the amount of the residual magnetism.

If we make this experiment at a point in the first stage

---

[1] Abstract of a Friday Evening Discourse delivered at the Royal Institution, on May 22, 1891, by J. A. Ewing, M.A., F.R.S., Professor of Applied Mechanics and Mechanism in the University of Cambridge.

(*a*), we shall find, as Lord Rayleigh has shown, little or no residual magnetism; if we make it at any point in the second stage (*b*), we shall find very much residual magnetism; and if we make it at any point in the third stage (*c*), we shall find only a little more residual magnetism than we should have found by making the experiment at the end of stage *b*. That part of the turning of the molecules which goes on in stage *a* contributes nothing to the residual magnetism. That part which goes on in stage *c* contributes little. But that part of the turning which goes on in stage *b* contributes very much.

In some specimens of magnetic metal we find a much sharper separation of the three stages than in others. By applying strain in certain ways it is possible to get the stages very clearly separated. Fig. 2, a beautiful instance of that, is taken from a paper by Mr. Nagaoka—one of an able band of Japanese workers who are bidding fair to repay the debt that Japan owes for its learning to the West. It shows how a piece of nickel which is under the joint action of pull and twist becomes magnetized in a growing magnetic field. There the first stage is exceptionally prolonged, and the second stage is extraordinarily abrupt.

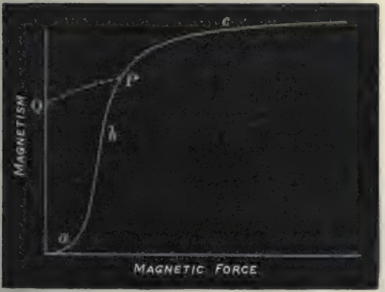

Fig. 1.

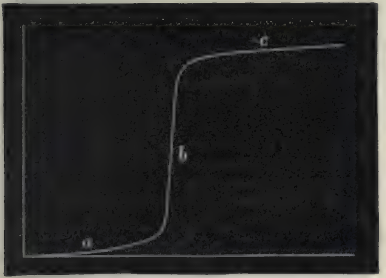

Fig. 2.

The bearing of all this on the molecular theory will be evident when we turn to these models, consisting of an assemblage of little pivoted magnets, which may be taken to represent, no doubt in a very crude way, the molecular structure of a magnetizable metal. I have here some large models, where the pivoted magnets are pieces of sheet steel, some cut into short flat bars, others into diamond shapes with pointed ends, others into shapes resembling mushrooms or umbrellas, and in these the magnetic field is produced by means of a coil of insulated wire wound on a large wooden frame below the magnets. Some of these are arranged with the pivots on a gridiron or lazy-tongs of jointed wooden bars, so that we may readily distort them, and vary the distances of the pivots from one another, to imitate some of the effects of strain in the actual solid. But to display the experiments to a large audience a lantern model will serve best. In this one the magnets are got by taking to pieces numbers of little pocket compasses. The pivots are cemented to a glass plate, through which the light passes in such a way as to project the shadows of the magnets on the screen. The magnetic force is applied by means of two coils, one on either side of the assemblage of magnets and out of the way of the light, which together produce a nearly uniform magnetic field throughout the whole group. You see this when I make manifest the field in a well-known fashion, by dropping iron filings on the plate.

Fig. 3.

We shall first put a single pivoted magnet on the plate. So long as no field acts it is free to point anyhow—there is no direction it prefers to any other. As soon as I apply even a very weak field it responds, turning at once into the exact direction of the applied force, for there was nothing (beyond a trifling friction at the pivot) to prevent it from turning.

Now try two magnets. I have cut off the current, so that there is at present no field, but you see at once that the pair has, so to speak, a will of its own. I may shake or disturb them as I please, but they insist on taking up a position (Fig. 3) with the north end of one as close as possible to the south end of the other. If disturbed they return to it: this configuration is highly stable. Watch what happens when the magnetic field acts with gradually growing strength. At first, so long as the field is weak (Fig. 4), there is but little deflection; but as the deflection increases it is evident that the stability is being lost, the state is getting more and more critical, until (Fig. 5) the tie that holds them together seems to break, and they suddenly turn, with violent swinging, into almost perfect alignment with the magnetic force H. Now I gradually remove the force, and you see that they are slow to return, but a stage comes when they swing back, and a

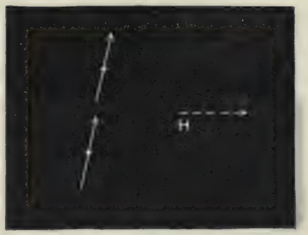

Fig. 4.

complete removal of the force brings them into the condition with which we began (Fig. 3).

If we were to picture a piece of iron as formed of a vast number of such pairs of molecular magnets, each pair far enough from its neighbours to be practically out of reach of their magnetic influence, we might deduce many of the observed magnetic properties, but not all.

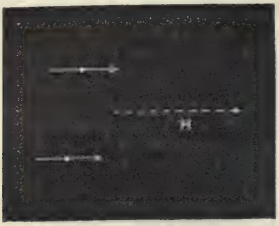

Fig. 5.

In particular, we should not be able to account for so much residual magnetism as is actually found. To get that, the molecules must make new connections when the old ones are broken; their relations are of a kind more complex than the quasi-matrimonial one which the experiment exhibits. Each molecule is a member of a larger community, and has probably many neighbours close enough to affect its conduct.

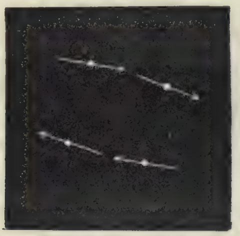

Fig. 6.

We get a better idea of what happens by considering four magnets (Fig. 6). At first, in the absence of deflecting magnetic force, they group themselves in stable pairs—in one of a number of possible combinations. Then—as in the former case—when magnetic force is applied, they are at first slightly deflected, in a manner that exactly tallies with what I have called the stage *a* of the magnetizing process. Next comes instability. The original ties break up, and the magnets swing violently round; but finding a new possibility of combining (Fig. 7), they take to that. Finally, as the field is further strengthened, they are drawn into perfect alignment with the applied magnetic force (Fig. 8).

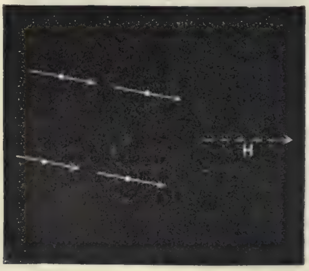

Fig. 7.

We see the same three stages in a multiform group (Figs. 9, 10, 11). At first, the group, if it is shuffled by any casual disturbance, arranges itself at random in lines that give no resultant polarity (Fig. 9). A weak force produces no more than slight quasi-elastic deflections; a stronger force breaks up the old lines, and forms new ones more favourably inclined to the direction of the force (Fig. 10). A very strong force brings about saturation (Fig. 11).

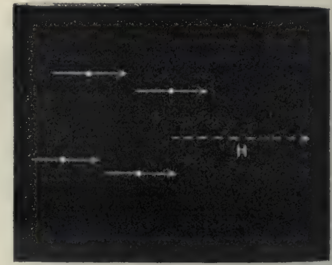

Fig. 8.

In an actual piece of iron there are multitudes of groups lying differently directed to begin with—perhaps also different as regards the spacing of their members. Some enter the second stage while others are still in the first, and so on. Hence, the curve of magnetization does not consist of perfectly sharp steps, but has the rounded outlines of Fig. 1.

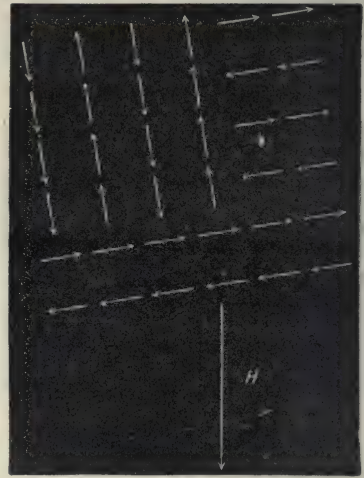

Fig. 9.

Notice, again, how the behaviour of these assemblages of elementary magnets agrees with what I have said about residual magnetism. If we stop strengthening the field before the first stage is passed—before any of the magnets have become unstable and have tumbled round into new places—the small deflection simply disappears, and there is no residual effect on the configuration of the group. But if we carry the process far enough to have unstable deflections, the effects of these persist when the force is removed, for the magnets then retain the new grouping into which they have fallen (Fig. 10). And again, the quasi-elastic deflections which go on during the third stage do not add to the residual magnetism.

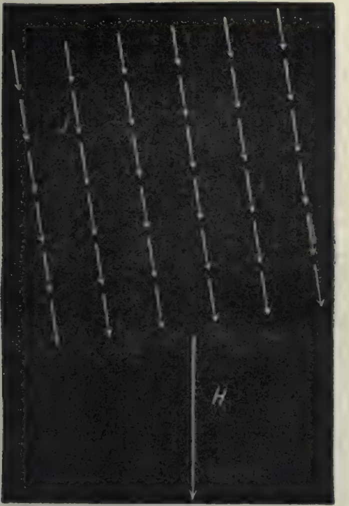

Fig. 10.

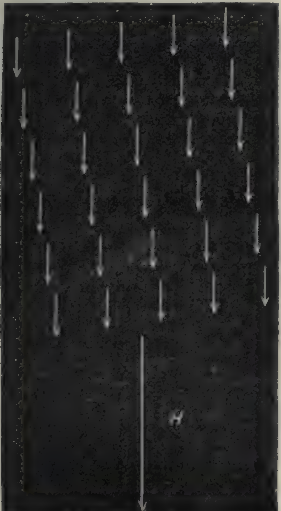

Fig. 11.

Notice, further, what happens to the group if after applying a magnetic force in one direction and removing it, I begin to apply force in the opposite direction. At first there is little reduction of the residual polarity, till a stage is reached when instability begins, and then reversal occurs with a rush. We thus find a close imitation of all the features that are actually observed when iron or any of the other magnetic metals is carried through a cyclic magnetizing process (Fig. 12). The effect of any such process is to form a *loop* in the curve which expresses the relation of the magnetism to the magnetizing force. The changes of magnetism always lag behind the changes of magnetizing force. This tendency to lag behind is called magnetic *hysteresis*.

We have a manifestation of hysteresis whenever a magnetic metal has its magnetism changed in any manner through changes in the magnetizing force, unless indeed the changes are so minute as to be confined to what I have called the first stage (*a*, Fig. 1). Residual magnetism is only a particular case of hysteresis.

Hysteresis comes in whatever be the character or cause of the magnetic change, provided it involves such deflections on the part of the molecules as make them become unstable. The unstable movements are not reversible with respect to the agent which produces them; that is to say, they are not simply undone step by step as the agent is removed.

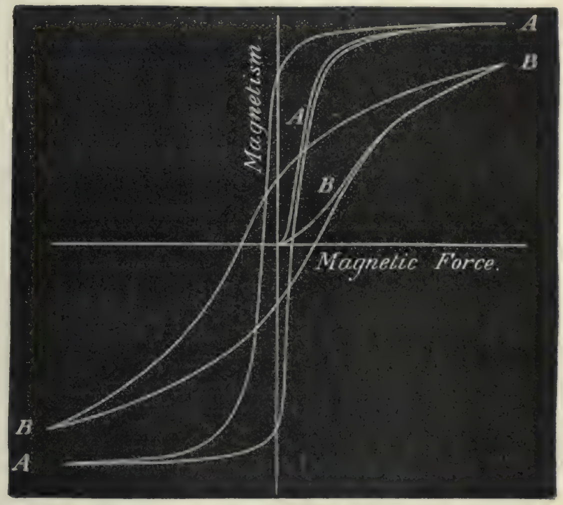

Fig. 12.—Cyclic reversal of magnetization in soft iron (AA), and in the same iron when hardened by stretching (BB).

We know, on quite independent grounds, that when the magnetism of a piece of iron or steel is reversed, or indeed cyclically altered in any way, some work is spent in performing the operation—energy is being given to the iron at one stage, and is being recovered from it at another; but when the cycle is taken as a whole, there is a net loss, or rather a waste of energy. It may be shown that this waste is proportional to the area of the loop in our diagrams. This energy is dissipated; that is to say, it is scattered and rendered useless: it takes the form of heat. The iron core of a transformer, for instance, which is having its magnetism reversed with every pulsation of the alternating current, tends to become hot for this very reason; indeed, the loss of energy which happens in it, in consequence of magnetic hysteresis, is a serious drawback to the efficiency of alternating-current systems of distributing electricity. It is the chief reason why they require much more coal to be burnt, for every unit of electricity sold, than direct-current systems require.

The molecular theory shows how this waste of energy occurs. When the molecule becomes unstable and tumbles violently over, it oscillates and sets its neighbours oscillating, until the oscillations are damped out by the eddy currents of electricity which they generate in the surrounding conducting mass. The useful work that can be got from the molecule as it falls over is less than the work that is done in replacing it during the return portion of the cycle. This is a simple mechanical deduction from the fact that the movement has unstable phases.

I cannot attempt, in a single lecture, to do more than glance at several places where the molecular theory seems to throw a flood of light on obscure and complicated facts, as soon as we recognize that the constraint of the molecules is due to their mutual action as magnets.

It has been known since the time of Gilbert that vibration greatly facilitates the process of magnetic induction. Let a piece of iron be briskly tapped while it lies in the magnetic field, and it is found to take up a large addition to its induced magnetism. Indeed, if we examine the successive stages of the process while the iron is kept vibrating by being tapped, we find that the first stage (*a*) has practically disappeared, and there is a steady and rapid growth of magnetism almost from the very first. This is intelligible enough. Vibration sets the molecular magnets oscillating, and allows them to break their primitive mutual ties and to respond to weak deflecting forces. For a similar reason, vibration should tend to reduce the residue of magnetism which is left when the magnetizing force is removed, and this, too, agrees with the results of observation.

Perhaps the most effective way to show the influence of vibration is to apply a weak magnetizing force first, before tapping. If the force is adjusted so that it nearly but not quite reaches the limit of stage (*a*), a great number of the molecular magnets are, so to speak, hovering on the verge of instability, and when the piece is tapped they go over like a house of cards, and magnetism is acquired with a rush. Tapping always has some effect of the same kind, even though there has been no special adjustment of the field.

And other things besides vibration will act in a similar way, precipitating the break-up of molecular groups when the ties are already strained. Change of temperature will sometimes do it, or the application or change of mechanical strain. Suppose, for instance, that we apply pull to an iron wire while it hangs in a weak magnetic field, by making it carry a weight. The first time that we put on the weight, the magnetism of the wire at once increases, often very greatly, in consequence of the action I have just described (Fig. 13). The molecules have been on the verge of turning, and the slight strain caused by the weight is enough to make them go. Remove the weight, and there is only a comparatively small change in the magnetism, for the greater part of the molecular turning that was done when the weight was put on is not undone when it is taken off. Reapply the weight, and you find again but little change, though there are still traces of the kind of action which the first application brought about. That is to say, there are some groups of molecules which, though they were not broken up in the first application of the weight, yield now, because they have lost the support they then obtained from neighbours that have now entered into new combinations. Indeed, this kind of action may often be traced, always diminishing in amount, during several successive applications and removals of the load (see Fig. 13), and it is only when the process of loading has been many times repeated that the magnetic change brought about by loading is just opposite to the magnetic change brought about by unloading.

Whenever, indeed, we are observing the effects of an alteration of physical condition on the magnetism of iron, we have to distinguish between the primitive effect, which is often very great and is not reversible, and the ultimate effect, which is seen only after the molecular structure has become somewhat settled through many repetitions of the process. Experiments on the effects of temperature, of strain, and so forth, have long ago shown this distinction to be exceedingly important: the molecular theory makes it perfectly intelligible.

Further, the theory makes plain another curious result of experiment. When we have loaded and unloaded the iron wire many times over, so that the effect is no longer complicated by the primitive action I have just described, we still find that the magnetic changes which occur while the load is being put on are not simply undone, step by step, while the load is being taken off. Let the whole load be divided into several parts, and you will see that the magnetism has two different values, in going up and in coming down, for one and the same intermediate value of the load. The changes of magnetism lag behind the changes of load: in other words, there is *hysteresis* in the relation of the magnetism to the load (Fig. 14). This is because some of the molecular groups are every time being broken up during the loading, and re-established during the unloading, and that, as we saw already, involves hysteresis. Consequently, too, each loading and unloading requires the expenditure of a small quantity of energy, which goes to heat the metal.

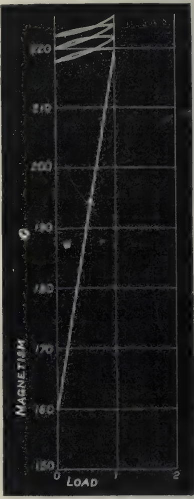

Fig. 13.—Effects of loading a soft iron wire in a constant field.

Moreover, a remarkably interesting conclusion follows. This hysteresis, and consequent dissipation of energy, will also happen though there be no magnetization of the piece as a whole: it depends on the fact that the molecules are magnets. Accordingly, we should expect to find, and experiment confirms this (see Phil. Trans., 1885, p. 614), that if the wire is loaded and unloaded, even when no magnetic field acts and there is no magnetism, its physical qualities which are changed by the load will change in a manner involving hysteresis. In particular, the length will be less for the same load during loading than during unloading, so that work may be wasted in every cycle of loads. There can be no such thing as perfect elasticity in a magnetizable metal, unless, indeed, the range of the strain is so very narrow that none of the molecules tumble through unstable states. This may have something to do with the fact, well known to engineers, that numerous repetitions of a straining action, so slight as to be safe enough in itself, have a dangerous effect on the structure of iron or steel.

Another thing on which the theory throws light is the phenomenon of time-lag in magnetization. When a piece of iron is put into a steady magnetic field, it does not take instantly all the magnetism that it will take if time be allowed. There is a gradual creeping up of the magnetism, which is most noticeable when the field is weak and when the iron is thick. If you will watch the manner in which a group of little magnets breaks up when a magnetic force is applied to it, you will see that the process is one that takes time. The first molecule to yield is some outlying one which is comparatively unattached—as we may take the surface molecules in the piece of iron to be. It falls over, and then its neighbours, weakened by the loss of its support, follow suit, and gradually the disturbance propagates itself from molecule to molecule throughout the group. In a very thin piece of iron—a fine wire, for instance—there are so many surface molecules, in comparison with the whole number, and consequently so many points which may become origins of disturbance, that the breaking up of the molecular communities is too soon over to allow much of this kind of lagging to be noticed.

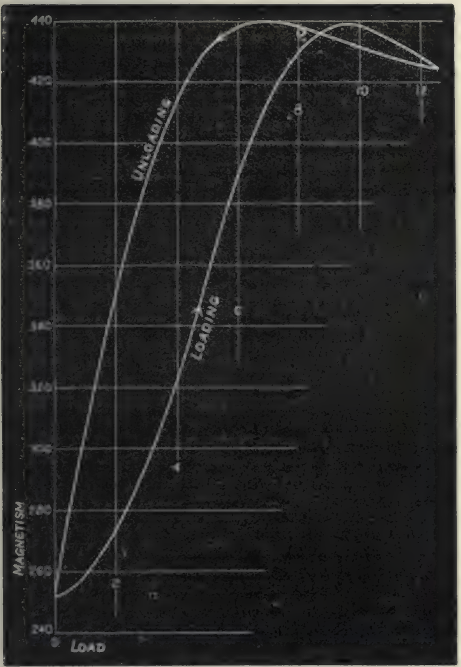

FIG. 14.—Cycle of loading and unloading.

Effects of temperature, again, may be interpreted by help of the molecular theory. When iron or nickel or cobalt is heated in a weak magnetic field, its susceptibility to magnetic induction is observed to increase, until a stage is reached, at a rather high temperature, when the magnetic quality vanishes almost suddenly and almost completely. Fig. 15, from one of Hopkinson's papers, shows what is observed as the temperature of a piece of steel is gradually raised. The sudden loss of magnetic quality occurs when the metal has become red-hot; the magnetic quality is recovered when it cools again sufficiently to cease to glow. Now, as regards the first effect—the increase of susceptibility with increase of temperature—I think that is a consequence of two independent effects of heating. The structure is expanded, so that the molecular centres lie further apart. But the freedom with which the molecules obey the direction of any applied magnetic force is increased not by that only, but perhaps even more by their being thrown into vibration. When the field is weak, heating consequently assists magnetization, sometimes very greatly, by hastening the passage from stage *a* to stage *b* of the magnetizing process. And it is at least a conjecture worth consideration whether the sudden loss of magnetic quality at a higher temperature is not due to the vibrations becoming so violent as to set the molecules spinning, when, of course, their polarity would be of no avail to produce magnetization. We know, at all events, that when the change from the magnetic to the non-magnetic state occurs, there is a profound molecular change, and heat is absorbed which is given out again when the reverse change takes place. In cooling from a red heat, the iron actually extends at the moment when this change takes place (as was shown by Gore), and so much heat is given out that (as Barrett observed) it reglows, becoming brightly red, though, just before the change, it had cooled so far as to be quite dull. [Experiment, exhibiting retraction and re-glow in cooling, shown by means of a long iron wire, heated to redness by the electric current.] The changes which occur in iron and steel about the temperature of redness are very complex, and I refer to this as only one possible direction in which a key to them may be sought. Perhaps the full explanation belongs as much to chemistry as to physics.

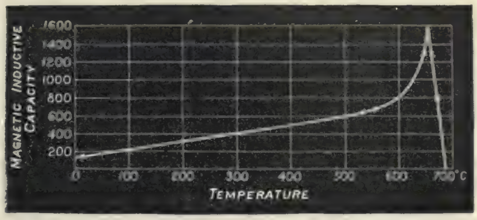

FIG. 15.—Relation of magnetic inductive capacity to temperature in hard steel (Hopkinson).

An interesting illustration of the use of these models has reached me, only to-day, from New York. In a paper just published in the *Electrical World* (reprinted in the *Electrician* for May 29, 1891), Mr. Arthur Hoopes supports the theory I have laid before you by giving curves which show the connection, experimentally found by him, between the resultant polarity of a group of little pivoted magnets and the strength of the magnetic field, when the field is applied, removed, reversed, and so on. I shall draw these curves on the screen, and rough as they are, in consequence of the limited number of magnets, you see that they succeed remarkably well in reproducing the features which we know the curves for solid iron to possess.

It may, perhaps, be fairly claimed that the models whose behaviour we have been considering have a wider application in physics than merely to elucidate magnetic processes. The molecules of bodies may have polarity which is not magnetic at all—polarity, for instance, due to static electrification—under which they group themselves in stable forms, so that energy is dissipated whenever these are broken up and rearranged. When we strain a solid body beyond its limit of elasticity, we expend work irrecoverably in overcoming, as it were, internal friction. What is this internal friction due to but the breaking and making of molecular ties? And if internal friction, why not also the surface friction which causes work to be spent when one body rubs upon another? In a highly suggestive passage of one of his writings,[1] Clerk Maxwell threw out the hint that many of the irreversible processes of physics are due to the breaking up and reconstruction of molecular groups. The models help us to realize Maxwell's notion, and, in studying them to-night, I think we may claim to have been going a step or two forward where that great leader pointed the way.

THE SUN'S MOTION IN SPACE.

SCIENCE needed two thousand years to disentangle the earth's orbital movement from the revolutions of the other planets, and the incomparably more arduous problem of distinguishing the solar share in the confused multitude of stellar displacements first presented itself as possibly tractable little more than a century ago. In the lack for it as yet of a definite solution there is, then, no ground for surprise, but much for satisfaction in the large measure of success attending the strenuous attacks of which it has so often been made the object.

Approximately correct knowledge as to the direction and velocity of the sun's translation is indispensable to a profitable study of sidereal construction; but apart from some acquaintance with the nature of sidereal construction, it is difficult, if not impossible, of attainment. One, in fact, presupposes the other. To separate a common element of motion from the heterogeneous shiftings upon the sphere of three or four thousand stars is a task practicable only under certain conditions. To begin with, the proper motions investigated must be established with *general* exactitude. The errors inevitably affecting them must be such as pretty nearly, in the total upshot, to neutralize one another. For should they run mainly in one direction, the result will be falsified in a degree enormously disproportionate to their magnitude. The adoption, for instance, of a system of declinations as much as 1″ of arc astray, might displace to the extent of 10° north or south the point fixed upon as the apex of the sun's way (see L. Boss, *Astr. Jour.*, No. 213). Risks on this score, however, will become less formidable with the further advance of practical astronomy along a track definable as an asymptote to the curve of ideal perfection.

Besides this obstacle to be overcome, there is another which it will soon be possible to evade. Hitherto, inquiries into the solar movement have been hampered by the necessity for preliminary assumptions of some kind as to the relative distances of classes of stars. But all such assumptions, especially when applied to selected lists, are highly insecure; and any fabric reared upon them must be considered to stand upon treacherous ground. The spectrographic method, however, here fortunately comes into play. "Proper motions" are only angular velocities. They tell nothing as to the value of the perspective element they may be supposed to include, or as to the real rate of going of the bodies they are attributed to, until the size of the sphere upon which they are measured has been otherwise ascertained. But the displacements of lines in stellar spectra give directly the actual velocities relative to the earth of the observed stars. The question of their distances is, therefore, at once eliminated. Now the radial component of stellar motion is mixed up, precisely in the same way as the tangential component, with the solar movement; and since complete knowledge of it, in a sufficient number of cases, is rapidly becoming accessible, while knowledge of tangential velocity must for a long time remain partial or uncertain, the advantage of replacing the discussion of proper motions by that of motions in line of sight is obvious and immediate. And the admirable work carried on at Potsdam during the last three years will soon afford the means of doing so in the first, if only a preliminary investigation of the solar translation based upon measurements of photographed stellar spectra.

The difficulties, then, caused either by inaccuracies in star-catalogues or by ignorance of star-distances, may be overcome; but there is a third, impossible at present to be surmounted, and not without misgiving to be passed by. All inquiries upon the subject of the advance of our system through space start with an hypothesis most unlikely to be true. The method uniformly adopted in them—and no other is available—is to treat the *inherent* motions of the stars (their so-called *motus peculiares*) as pursued indifferently in all directions. The steady drift extricable from them by rules founded upon the science of probabilities is presumed to be solar motion visually transferred to them in proportions varying with their remoteness in space, and their situations on the sphere. If this presumption be in any degree baseless, the result of the inquiry is *pro tanto* falsified. Unless the deviations from the parallactic line of the stellar motions balance one another on the whole, their discussion may easily be as fruitless as that of observations tainted with systematic errors. It is scarcely, however, doubtful that law, and not chance, governs the sidereal revolutions. The point open to question is whether the workings of law may not be so exceedingly intricate as to produce a grand sum-total of results which, from the geometrical side, may justifiably be regarded as casual.

The search for evidence of a general plan in the wanderings of the stars over the face of the sky has so far proved fruitless. Local concert can be traced, but no widely-diffused preference for one direction over any other makes itself definitely felt. Some regard, nevertheless, *must* be paid by them to the plane of the Milky Way; since it is altogether incredible that the actual construction of the heavens is without dependence upon the method of their revolutions.

The apparent anomaly vanishes upon the consideration of the profundities of space and time in which the fundamental design of the sidereal universe lies buried. Its composition out of an indefinite number of partial systems is more than probable; but the inconceivable leisureliness with which their mutual relations develop renders the harmony of those relations inappreciable by short-lived terrestrial denizens. "Proper motions," if this be so, are of a subordinate kind; they are indexes simply to the mechanism of particular aggregations, and have no definable connection with the mechanism of the whole. No considerable error may then be involved in treating them, for purposes of calculation, as indifferently directed; and the elicited solar movement may genuinely represent the displacement of our system relative to its more immediate stellar environment. This is perhaps the utmost to be hoped for until sidereal astronomy has reached another stadium of progress.

Unless, indeed, effect should be given to Clerk Maxwell's suggestion for deriving the absolute longitude of the solar apex from observations of the eclipses of Jupiter's satellites (Proc. Roy. Soc., vol. xxx. p. 109). But this is far from likely. In the first place, the revolutions of the Jovian system cannot be predicted with anything like the required accuracy. In the second place, there is no certainty that the postulated phenomena have any real existence. If, however, it be safe to assume that the solar system, cutting its way through space, virtually raises an ethereal counter-current, and if it be further granted that light travels faster *with* than *against* such a current, then indeed it becomes speculatively possible, through slight alternate accelerations and retardations of eclipses taking place respectively ahead of and in the wake of the sun, to determine his absolute path in space as projected upon the ecliptic. That is to say, the longitude of the apex could be deduced together with the resolved part of the solar velocity; the latitude of the apex, as well as the component of velocity perpendicular to the plane of the ecliptic, remaining, however, unknown.

---

[1] "Encyc. Brit.," Art. "Constitution of Bodies."

The beaten track, meanwhile, has conducted two recent inquirers to results of some interest. The chief aim of each was the detection of systematic peculiarities in the motions of stellar assemblages after the subtraction from them of their common perspective element. By varying the materials and method of analysis, Prof. Lewis Boss, Director of the Albany Observatory, hopes that corresponding variations in the upshot may betray a significant character. Thus, if stars selected on different principles give notably and consistently different results, the cause of the difference may with some show of reason be supposed to reside in specialities of movement appertaining to the several groups. Prof. Boss broke ground in this direction by investigating 284 proper motions, few of which had been similarly employed before (*Astr. Jour.*, No. 213). They were all taken from an equatorial zone 4° 20′ in breadth, with a mean declination of +3°, observed at Albany for the catalogue of the Astronomische Gesellschaft, and furnished data accordingly for a virtually independent research of a somewhat distinctive kind. It was carried out to three separate conclusions. Setting aside five stars with secular movements ranging above 100″, Prof. Boss divided the 279 left available into two sets—one of 135 stars brighter, the other of 144 stars fainter, than the eighth magnitude. The first collection gave for the goal of solar translation a point about 4° north of α Lyræ, in R.A. 280°, Decl. + 43°; the second, one some thirty-seven minutes of time to the west of δ Cygni, in R.A. 286°, Decl. + 45°. For a third and final solution, twenty-six stars moving 40″–100″ were rejected, and the remaining 253 classed in a single series. The upshot of their discussion was to shift the apex of movement to R.A. 289°, Decl. + 51°. So far as the difference from the previous pair of results is capable of interpretation, it would seem to imply a predominant set towards the north-east of the twenty-six swifter motions subsequently dismissed as prejudicial, but in truth the data employed were not accurate enough to warrant so definite an inference. The Albany proper motions, as Prof. Boss was careful to explain, depend for the most part upon the right ascensions of Bessel's and Lalande's zones, and are hence subject to large errors. Their study must be regarded as suggestive rather than decisive.

A better quality and a larger quantity of material was disposed of by the latest and perhaps the most laborious investigator of this intricate problem. M. Oscar Stumpe, of Bonn (*Astr. Nach.*, Nos. 2999, 3000) took his stars, to the number of 1054, from various quarters, if chiefly from Auwers's and Argelander's lists, critically testing, however, the movement attributed to each of not less than 16″ a century. This he fixed as the limit of secure determination, unless for stars observed with exceptional constancy and care. His discussion of them is instructive in more ways than one. Adopting, the additional computative burden imposed by it notwithstanding, Schönfeld's modification of Airy's formulæ, he introduced into his equations a fifth unknown quantity expressive of a possible stellar drift in galactic longitude. A negative result was obtained. No symptom came to light of "rotation" in the plane of the Milky Way.

M. Stumpe's intrepid industry was further shown in his disregard of customary "scamping" subterfuges. Expedients for abbreviation vainly spread their allurements; every one of his 2108 equations was separately and resolutely solved. A more important innovation was his substitution of proper motion for magnitude as a criterion of remoteness. Dividing his stars on this principle into four groups, he obtained an apex for the sun's translation corresponding to each as follows:—

Group.	Number of included stars.	Proper motion.	Apex.	
I. ...	551 ...	0″·16 to 0″·32 ...	R.A. 287°·4	Decl. + 42°
II. ...	340 ...	0·32 to 0·64 ...	,, 279·7	,, 40·5
III. ...	105 ...	0·64 to 1·28 ...	,, 287·9	,, 32·1
IV. ...	58 ...	1·28 and upwards	,, 285·2	,, 30·4

Here, again, we find a marked and progressive descent of the apex towards the equator with the increasing swiftness of the objects serving for its determination, leading to the suspicion that the most northerly may be the most genuine position, because the one least affected by stellar individualities of movement. By nearly all recent investigations, moreover, the solar *point de mire* has been placed considerably further to the east and nearer to the Milky Way, than seemed admissible to their predecessors; so that the constellation Lyra may now be said to have a stronger claim than Hercules to include it; and the necessity has almost disappeared for attributing to the solar orbit a high inclination to the medial galactic plane.

From both the Albany and the Bonn discussions, there emerged with singular clearness a highly significant relation. The mean magnitudes of the two groups into which Prof. Boss divided his 279 stars, were respectively 6·6 and 8·6, the corresponding mean proper motions 21″·9 and 20″·9. In other words, a set of stars on the whole six times brighter than another set owned a scarcely larger sum-total of apparent displacement. And that this approximate equality of movement really denoted approximate equality of mean distance was made manifest by the further circumstance that the secular journey of the sun proved to subtend nearly the same angle whichever of the groups was made the standpoint for its survey. Indeed, the fainter collection actually gave the larger angle (13″·73 as against 12″·39), and so far an indication that the stars composing it were, on an average, nearer to the earth than the much brighter ones considered apart.

A result similar in character was reached by M. Stumpe. Between the mobility of his star groups, and the values derived from them for the angular movement of the sun, the conformity proved so close as materially to strengthen the inference that apparent movement measures real distance. The mean brilliancy of his classified stars seemed, on the contrary, quite independent of their mobility. Indeed, its changes tended in an opposite direction. The mean magnitude of the slowest group was 6·0, of the swiftest 6·5, of the intermediate pair 6·7 and 6·1. And these are not isolated facts. Comparisons of the same kind, and leading to identical conclusions, were made by Prof. Eastman at Washington in 1889 (Phil. Society Bulletin, vol. xi. p. 143; Proceedings Amer. Association, 1889, p. 71).

What meaning can we attribute to them? Uncritically considered, they seem to assert two things, one reasonable, the other palpably absurd. The first—that the average angular velocity of the stars varies inversely with their distance from ourselves—few will be disposed to doubt; the second—that their average apparent lustre has nothing to do with greater or less remoteness—few will be disposed to admit. But, in order to interpret truly, well-ascertained if unexpected relationships, we must remember that the sensibly moving stars used to determine the solar translation are chosen from a multitude sensibly fixed; and that the proportion of stationary to travelling stars rises rapidly with descent down the scale of magnitude. Hence a mean struck in disregard of the zeros, is totally misleading; while the account is no sooner made exhaustive than its anomalous character becomes largely modified. Yet it does not wholly disappear. There is some warrant for it in nature. And its warrant may perhaps consist in a preponderance, among suns endowed with high *physical* speed, of small, or slightly luminous, over powerfully radiative bodies. Why this should be so, it would be futile, even by conjecture, to attempt to explain.

A. M. CLERKE.

NOTES.

THE respect in which science is held in Germany was strikingly displayed on Tuesday, when Prof. Virchow celebrated his seventieth birthday. The occasion was regarded as one of national importance, and much honour was done to the investigator who, in the course of his great career, has given a fresh impetus to so many departments of research. In the morning, congratulations were offered to him in the large hall of the Kaiserhof Hotel, Berlin. The room was crowded with professors, academicians, and men of science from all parts of Europe; and on a long table were innumerable presents, medals, diplomas, and addresses. Short speeches were delivered on behalf of a series of deputations, the first of which was headed by Dr. Bartsch, one of the chief officials of the Ministry. A deputation, consisting of the professors of the Medical Faculty of the University of Berlin, and headed by Prof. Hirsch, the Dean, was followed by another from the Berlin Academy of Science, for which Prof. von Helmholtz spoke. Dr. von Forckenbeck, the Burgomaster of Berlin, heading a deputation from the Municipality of the capital, presented Prof. Virchow with the freedom of the city, referring gratefully to all that he had done to improve the health of the community. An address and medal, sent by English scientific bodies, were presented by Dr. Simon and Mr. Horsley, and then came congratulatory addresses from the Medical Faculties of many foreign cities, including Amsterdam, Brussels, Stockholm, St. Petersburg, Moscow, Pavia, and Tokio. The Virchow gold medal, for which contributions had been sent from all sections of the medical world, was presented by Prof. Waldeyer. Frau Virchow received a silver replica, and bronze copies were given to the other members of the family and to the scientific bodies which had subscribed for the medal. In the afternoon, a second meeting was held in the large hall of the Pathological Institute, where, as the Berlin correspondent of the *Times* says, "an almost endless procession of learned bodies and other corporations, presenting gifts and addresses, defiled before Prof. Virchow." The day's proceedings lasted from 10 a.m. to 4 p.m.; but it was noted, we are glad to say, that Prof. Virchow "seemed in no way fatigued by his exertions." More speeches were delivered in the evening, when a "Commers," or reunion, of his friends and admirers was held in Kroll's Theatre.

THE ordinary general meeting of the Institution of Mechanical Engineers will be held on Wednesday evening, October 28, and Thursday evening, October 29, at 25 Great George Street, Westminster. The chair will be taken at half-past seven p.m. on each evening by the President, Mr. Joseph Tomlinson. The ballot lists for the election of new members, associates, and graduates having been previously opened by the Council, the names of those elected will be announced to the meeting. The nomination of officers for election at the next annual general meeting will take place. The following papers will be read and discussed, as far as time permits:—On some details in the construction of modern Lancashire boilers, by Mr. Samuel Boswell (Wednesday); First Report to the Alloys Research Committee, by Prof. W. C. Roberts-Austen, C.B., F.R.S. (Thursday).

THE anniversary meeting of the Mineralogical Society will be held in the apartments of the Geological Society, Burlington House, on Tuesday, November 10, at 8 p.m.

THE International Congress of Analytical Chemists and Microscopists met at Vienna on October 12 and 13. The subject discussed was the adulteration of food-stuffs.

GREAT preparations are being made for the meeting of the Australasian Association for the Advancement of Science which is to be held at Hobart, Tasmania, in January next. It is expected that the meeting will be most successful. The members of the Royal Society of Tasmania are congratulating themselves that Mr. Giffen, the eminent statistician and political economist, proposes to attend the meeting and to read a paper. His Excellency Sir R. G. C. Hamilton, who will preside, tried some time ago to secure the presence of Prof. Huxley also. Prof. Huxley replied that he had pleasant recollections of Tasmania as it was forty-three years ago, and it would have interested him very much to revisit the colony and compare the present with the past, but he regretted that the state of his health prevented him from accepting the invitation.

ONE of the last surviving pupils of Dalton died at Bolton on October 6. Mr. William B. Watson was born at Bolton in January 1812, and educated at the local grammar-school. He afterwards studied for some years under Dalton at Manchester, and became so devoted to his teacher that he was chosen to help in the nursing of Dr. Dalton during the illness following his first paralytic seizure. Mr. Watson also assisted in many of Dalton's researches, and is mentioned by name in his papers in the Philosophical Transactions on the composition of the atmosphere as "an ingenious pupil of mine, Mr. William Barnett Watson." Mr. Watson had a wonderful store of anecdotes about his old master, and used to speak with pride of the great care he took in all his work. As an instance may be mentioned the pains he took to compensate for his colour-blindness. Dalton used to say that the bloom on a maiden's cheek and the colour of a faded green table-cloth seemed to him one and the same, and that he could only distinguish between the fruit and leaves on an apple-tree by their difference in shape. Dalton had a book containing different colours of floss silk, and below these he carefully noted the names given to them by non-colour-blind people, adding what the colour appeared to him to be. Careful methods such as these enabled him generally to give an accurate description of the colour of a precipitate. Mr. Watson carried on, together with his elder brother, Mr. H. H. Watson, a very extensive practice as an analytical chemist, and was much consulted in legal and commercial cases.

THE death of Mr. Charles Smith Wilkinson, the Government Geologist of New South Wales, will be felt as a great loss, especially in his own colony. His enthusiasm in the cause of geological science, his extensive knowledge of the geological features of Eastern Australia, and his admirable personal qualities had made him greatly valued. Mr. Wilkinson was an original member of the Linnean Society of New South Wales, and president of that Society in the years 1883 and 1884. His death, which took place at the age of forty-seven, on the 26th of August, was announced to the Society on the evening of the same day.

La Nature announces the death of Prof. Edouard Lucas, who presided over the Sections of Mathematics and Astronomy at the recent meeting, at Marseilles, of the French Association for the Advancement of Science. A pile of plates fell one day after dinner while he was at Marseilles, and he happened to be struck in the cheek by a fragment of the broken earthenware. The hurt became more and more troublesome, and after his return to Paris he died of erysipelas. M. Lucas was forty-nine years of age. He was a brilliant lecturer, and the author of several valuable books, the most important of which is his "Récréations Mathématiques."

APPLICATION has been made for 20,000 square feet of space for the electrical display from Great Britain at the "World's Fair" at Chicago. *Electricity*, the new weekly journal published at Chicago, remarks that this application should "set at rest all doubts in regard to the extent of the exhibit to be made by British manufacturers of electrical apparatus."

MR. C. E. KELWAY is now showing at the Royal Naval Exhibition an invention which promises to be of great practical value. It consists of an apparatus for marine and general electrical signalling. A number of electric incandescent lamps are placed in a suitable frame, from which insulated wires are led to a key-board, similar to those used in typewriters, or compound-switch. A key is appropriated for each letter of the alphabet and for numerals. On this key being depressed the electric current is switched on to the lamps representing the corresponding letter, which is at once shown to the observer. On the pressure being removed the lights disappear, and the next letter, or numeral, is in like manner shown, the words being spelt out at a rate more quickly than by the Morse system. Mr. Kelway claims that the applications to which this invention can be put are numerous. It might, he thinks, be of great service in naval tactics, and prove invaluable for military purposes. He also points out that it would enable mercantile vessels to communicate readily with each other and with the shore.

A CORRESPONDENT asks whether there are any firms which supply magic lantern slides dealing with geological subjects.

THE marine laboratory of biology and zoology, which is to be instituted at Bergen next year, will be open to any foreign investigators who may desire to study the marine fauna of that part of Scandinavia.

THE complete list of subscribers to the memorial to Bishop Berkeley, which has just been issued, contains the names of Profs. Huxley and Tyndall, in company with the Archbishop of Dublin and a number of bishops and deans. Mr. Gladstone and Mr. Balfour meet together in the same list. The memorial is a beautiful recumbent figure by Mr. Bruce Joy, R.A., which has been placed in Cloyne Cathedral. The inscription to be placed on the monument has not yet been announced.

THE Sociedad Cientifica "Antonio Alzate," of Mexico, who have lately moved into new quarters, have just resolved to throw open their scientific library to the general public. They are appealing on this ground to all foreign professors and scientific authors to send copies of their works to the library.

THE Engineers' and Architects' Institute of Vienna have resolved to petition the Austrian Government that engineer attachés should in future be appointed to the embassies and legations in London, Berlin, Paris, St. Petersburg, Rome, Washington, and to one Oriental city to be hereafter selected.

THE Royal Horticultural Society has issued a list of fruits which might be profitably cultivated by cottagers and small farmers in this country. The list (to which are added notes on planting, pruning, and manuring) ought to be widely distributed. It contains all the information that is really necessary for the development of a most important industry.

ACCORDING to a telegram sent from San Francisco, a severe shock of earthquake was felt there on October 11, but no damage was done. At Napa, California, where a heavy shock was experienced, the chimneys were thrown to the ground, and several buildings were shattered. The State Insane Asylum is reported to have been damaged, fissures being made in the walls. The inmates were seized with panic.

WE take from *La Nature* of the 3rd inst. the following particulars respecting the destructive cyclone which visited Martinique on the 28th of August last. The curve of a Richard barograph shows that the barometer commenced to fall about 2 p.m., when it stood at 29·92 inches, while between 7 and 8 p.m. it fell from 29·72 inches to 28·70 inches. The wind at this time, too, reached its greatest violence, and continued with hurricane force for several hours, passing alternately from N.E. to South. The recovery of the barometric pressure was equally rapid, the reading being about 29·70 inches before 10 p.m. M. Sully, of Saint Pierre, writes that the lightning was constant, with varying intensity before and after the passage of the centre. The sound of the thunder was scarcely perceptible, owing to the howling of the wind and the noise caused by the falling roofs and houses. Globular lightning was seen on all sides during the hurricane; the country folks speak of globes of fire which traversed the air for several minutes, and burst about two feet above the ground. All the towns and villages were greatly damaged, the crops destroyed, and that usually verdant country presented the appearance of the depth of the most severe winter. The deaths are said to be 420 in number.

IN the review of September in the U.S. Pilot Chart, it is pointed out that the month was unusually stormy on the North Atlantic, as indicated by the storm tracks plotted on the chart. Two of these tracks, however, represent August storms, one of them being the track of the Martinique hurricane, and another the track of the hurricane that passed east of Bermuda on August 27. The Martinique hurricane, it appears, moved west-north-west along a somewhat irregular track, crossing over Puerto Rico, Turk's Island, Crooked Island, and lower Florida, finally dying out in the north-eastern Gulf. This unusual course makes it of special interest, and its failure to recurve seems to have been due, possibly, to the opposition of the Bermuda hurricane, in a manner similar to the deflection towards Vera Cruz of the Cuban hurricane of September 1888. The Bermuda hurricane appears to have originated about 300 miles S.W. of the Cape Verde Islands on August 19.

THE correspondent of the *Times* at Alexandria telegraphed on October 11 that three colossal statues, ten feet high, of rose granite, had just been found at Aboukir, a few feet below the surface. The discovery was made from indications furnished to the Government by a local investigator, Daninos Pasha. The first two represent in one group Rameses II. and Queen Hentmara seated on the same throne. This is unique among Egyptian statues. The third statue represents Rameses standing upright in military attire, a sceptre in his hand and a crown upon his head. Both bear hieroglyphic inscriptions, and both have been thrown from their pedestals face downwards. Their site is on the ancient Cape Zephyrium, near the remains of the Temple of Venus at Arsinoe. Relics of the early Christians have been found in the same locality.

WE learn from the *Brighton Herald* that a discovery full of interest to archæologists has been made in Sussex. During some excavations near the depot of the Artillery Volunteers at Southover, Lewes, the workmen uncovered as many as twenty-eight skeletons. They were all buried close to the surface, and within an area of about 130 feet by 50 feet. As there were skeletons of women as well as of men, it is concluded that the site was not that of a battle-field, but of a place of burial. A similar find was made in 1830 at Malling Hill, which is not far distant. The remains now found were accompanied by a large number of weapons and ornaments, the characteristic features of which point to the fact of their being Anglo-Saxon. The skeletons have been reinterred, but the weapons and other articles have been placed in the museum of the Sussex Archæological Society at Lewes Castle.

MR. CLEMENT L. WALKER, while carrying on geological work in South-Western New Mexico, has also been pursuing archæological researches in that most interesting region during the last two years. He proposes to publish a detailed account of his investigations, and in the meantime he briefly records some of them in the August number of the *American Naturalist*, On the east, west, and middle branches of the Gila River, in the Mogollon Mountains, there is an extremely rough, wild, and broken tract; and here, in the rugged cliffs, are found great numbers of ancient cliff-dwellings. Mr. Webster devoted considerable time to the study of these dwellings, making plans and sketches, and copying the drawings of many of the more interesting and extensive hieroglyphics painted on the rocks. One of these ancient pueblos of the cliff-dwellers is situated in a lofty cliff which forms the side of a deep, narrow cañon extending out from the west branch of the Gila. This cliff-dwellers' village is in a fine state of preservation, and consists of upwards of twenty-eight rooms. Among the relics obtained in the rooms were specimens of several kinds of cloth, all made from the fibre of the Spanish dagger, matting of bear-grass. willow-work, sandals, cords of various sizes, feather-work, a ball and large skein of twine of the same material as the cloth, human and animal bones, stone utensils, great quantities of corn-cobs, corn, squash or pumpkin rinds, seeds and stems, corn-husks, beans, gourds, pottery, braided human hair of a brown colour, &c.; and last, but by no means least, a perfectly preserved cliff-dweller mummy. This was a mummy of a small child, with soft brown hair, similar to that found braided, only finer. It was closely wrapped in a considerable amount of two varieties of coarse cloth, woven from the fibre of the Spanish dagger, then wrapped in a large nicely-woven mat of bear-grass, and tied on by cords of the same material as the cloth to a small curiously-shaped board of cotton-wood.

SOME fine caves have lately been discovered near Southport, Tasmania. At the meeting of the Royal Society of Tasmania in June, an account of them was given by Mr. Morton, who had visited them. They are situated about four miles from Ida Bay, and a fairly good road leads to them. The entrance is through a limestone formation. A strong stream flows along the floor of the chambers. The first chamber reached by Mr. Morton and those who accompanied him showed some fine stalactites, and along the floor some fine stalagmites were seen. On the lights carried by the party being extinguished, the ceiling and sides of the caves seemed studded with diamonds, an effect due to millions of glow-worms hanging to the sides of the walls and from the ceilings. Further on, several chambers were explored, each revealing grander sights. The time at disposal being limited, the party had to return after traversing a distance of about three-quarters of a mile, but from what was observed the caves evidently extended a distance of three or four miles. The only living creatures seen were the glow-worms. These caves, under proper supervision, should become, Mr. Morton thinks, one of the great attractions of the south of Tasmania.

IN the Quarterly Statement of the Palestine Exploration Fund, it is announced that the first volume of the "Survey of Eastern Palestine," by Major Conder, has been issued to subscribers. It is accompanied by a map of the portion of country surveyed, special plans, and upwards of 350 drawings of ruins, tombs, dolmens, stone circles, inscriptions, &c. It is also announced that the new map of Palestine, so long in hand, is now ready. This map represents both sides of the Jordan, and extends from Baalbek in the north, to Kadesh Barnea in the south.

MR. E. R. MORSE contributes to the October number of the *Engineering Magazine*, a periodical issued at New York, an interesting paper on marble quarrying in the United States. Within recent years the use of American marble both in cemeteries and in buildings has become very extensive. Various foreign marbles, such as the African Red, Belgium Black, and Mexican Onyx, are employed in the interior decoration of buildings; but only Italian marble can be said to come really into competition with the American product, and the importation of this stone into the United States amounts only to about one-sixth of the value of the marble produced and sold at home. The quarrying of marble is practically limited at present to Tennessee, Georgia, Maryland, New York, Massachusetts, and Vermont. Large and valuable deposits may exist elsewhere, but the expense of testing deposits is so great, and the chances that the product of new quarries may prove unsaleable are so numerous, that Mr. Morse thinks that new marble fields are not likely to be developed soon.

THE "basking shark" (*Selache maxima*, L.) is apparently no very uncommon visitor in New Zealand waters. In the new volume of the Transactions and Proceedings of the New Zealand Institute, Mr. T. F. Cheeseman, Curator of the Auckland Museum, describes a specimen, over 34 feet long, which was stranded near the mouth of the Wade River. Mr. R. H. Shakspere, of Whangaparaoa, who saw the specimen very shortly after it was stranded, has informed Mr. Cheeseman that every spring several individuals of the same species can be seen near the entrance of the Wade River, and along the shores of Whangaparaoa Peninsula. He believes that they visit these localities in search of their food, which he thinks is composed of small *Medusæ* and other pelagic organisms. They can be easily recognized from their habit of swimming on the surface of the water, a portion of the back and the huge dorsal fin being usually exposed. It is from this circumstance, taken with the fact that their motions are very often slow and sluggish, that they have received the name of the "basking shark." They are easily approached and harpooned, and on the west coast of Ireland as many as five hundred have been taken in a single season. The liver often weighs as much as two tons, yielding six to eight barrels of oil. A few years ago, when sharks' oil was of greater value than it is at present, the oil from a single full-sized specimen would often realize from £40 to £50.

AT the meeting of the Linnean Society of New South Wales, on June 29, Mr. Froggatt exhibited some living beetles (fam. *Curculionidæ*), which afford a good example of protective coloration. They were found at Wellington, N.S.W., on the trunks of Kurrajong trees (*Sterculia*), the bark of which they resemble so closely in tint and general appearance that it was quite by accident Mr. Froggatt first recognized their true character.

MESSRS. GAUTHIER-VILLARS have sent us the "Annuaire" for 1891 of the Municipal Observatory of Montsouris. It contains, as usual, a great mass of carefully selected and well arranged information. We may especially note a collection of old meteorological observations made at Paris, and the following papers: Parisian climatology, by M. Léon Descroix; chemical analysis of the air and of waters, by M. Albert Lévy; thirteenth memoir on organic dust in the air and in waters, by Dr. Miquel.

MESSRS. G. L. ENGLISH AND CO., New York, have found it necessary to issue a supplement to the catalogue of minerals which they published in June 1890. So great has been the demand for minerals that they had three collectors at work during the summer—one in Europe, another in the south-western part of the United States and in Mexico, and a third in Colorado.

THE new number of the *Journal of Anatomy and Physiology* opens with some valuable notes by Dr. R. Havelock Charles, on the craniometry of some of the outcaste tribes of the

Panjab. He presents a series of tables drawn from the measurement of fifty skulls collected by him in the comparative anatomy museum of the Medical College, Lahore. These skulls are, in Dr. Charles's opinion, from individuals of aboriginal as distinguished from Aryan progeny, with the exception of certain megacephalic examples among the group of Mohammedan male types. In these exceptional cases descent may be derived from the more recent Mohammedan invaders, who were distinct both from the Aryan possessors on the one hand, and from the dispossessed aboriginal races on the other.

THE Department of Public Instruction in New South Wales has issued a second edition of "Wattles and Wattle-Barks," by J. H. Maiden. It appears as No. 6 of the Technical Education Series. The pamphlet is intended to supply Australian farmers, tanners, merchants, and others with authentic information in regard to the value of wattles. According to the author, the demand for good wattle-bark becomes greater every year, and the supply does not cope with it. The word "wattle," we may note, has become in Australia practically synonymous with "acacia."

AN interesting experiment has been lately made by M. Chabry, of the Société de Biologie, with regard to the pressure which can be produced by electrolytic generation of gas in a closed space. While the highest pressure before realized in this way was 447 atmospheres (Gassiot), M. Chabry has succeeded in getting as high as 1200; and the experiment was broken off merely because the manometer used got cracked (without explosion). The electrolyzed liquid was a 25 per cent. soda solution. Both electrodes were of iron: one was the hollow sphere in which the gas was collected; the other an inner concentric tube. The current had a strength of 1½ ampere, and was very constant during the experiment, which was merely one preliminary to a research in which very high pressures were desired.

THE first series of lectures given by the Sunday Lecture Society begins on Sunday afternoon, October 18, in St. George's Hall, Langham Place, at 4 p.m., when Sir James Crichton Browne, F.R.S., will lecture on "Brain Rust." Lectures will subsequently be given by Mr. Frank Kerslake, Mr. Walter L. Bicknell, Mr. W. E. Church, Prof. H. Marshall Ward, F.R.S., Mr. A. W. Clayden, and Sir Robert Ball, F.R.S.

AN important paper upon persulphates is contributed by Dr. Marshall, of Edinburgh, to the October number of the *Journal of the Chemical Society*. The anhydride of persulphuric acid, S_2O_7, was obtained by Berthelot in the year 1878, by subjecting a well-cooled mixture of sulphur dioxide and oxygen to the silent electrical discharge. He afterwards found that a substance possessing oxidizing properties, and which appeared to be persulphuric acid, was formed in solution during the electrolysis of fairly strong solutions of sulphuric acid; it appeared, in fact, to be identical with the substance obtained by dissolving his crystals of S_2O_7 in water. The anhydride does not dissolve in water without partial decomposition, a considerable proportion decomposing into sulphuric acid and oxygen, and hitherto no salts of persulphuric acid have been obtained in the solid state. Dr. Marshall has now succeeded in obtaining the potassium, ammonium, and barium salts in fine large crystals. During the course of an experiment in which an acid solution of potassium and cobalt sulphates was being electrolyzed in a divided cell, it was found that a quantity of small colourless crystals separated. A solution of these crystals in water gave only a faint precipitate with barium chloride, but on warming barium sulphate slowly separated and chlorine was evolved. The solution also liberated iodine from potassium iodide. The crystals were, in fact, potassium persulphate, KSO_4. It was next sought to prepare them from hydrogen potassium sulphate. A saturated solution of this salt was submitted to electrolysis in a similar apparatus, and at the end of two days a white crystalline deposit of potassium persulphate commenced to form. The crystals were from time to time removed until a considerable quantity of them had been accumulated. These, when recrystallized from hot water, yielded large tabular crystals, and sometimes long prisms when formed at the surface of the liquid. Analyses of pure samples yielded numbers agreeing perfectly with the formula KSO_4. From determinations of the conductivity of dilute solutions it would appear that the correct molecular formula is KSO_4 and not $K_2S_2O_8$. On ignition of the salt, oxygen and sulphuric anhydride are evolved and potassium sulphate is left. The crystals are not very soluble in water, 100 parts of water at 0° dissolving 1·77 part of KSO_4. The aqueous solution gradually decomposes, hydrogen potassium sulphate being formed and oxygen liberated. The pure freshly prepared solution is neutral to test paper. The solution yields no precipitate with any other salt by double decomposition, the persulphates of most other metals appearing to be more soluble than potassium persulphate. A solution of lead hydrate in potash yields a precipitate of lead peroxide on boiling. With silver nitrate no immediate precipitate is formed, but the liquid gradually acquires an inky appearance and after some time a black precipitate of silver peroxide, AgO, is deposited. It would appear that silver persulphate is dissolved by water. Fehling's solution gives a red precipitate of copper peroxide. Ferrous sulphate is rapidly oxidized to ferric with considerable rise of temperature. Organic colouring matters, such as litmus, are bleached. Alcohol is oxidized to aldehyde in presence of water, but absolute alcohol has no action on solid potassium persulphate. The pure crystals have a cooling saline taste, which leaves a peculiar after-taste. The impure salt evolves ozone slowly. Freshly prepared crystals have no odour, but after a time they emit a peculiar pungent odour quite different from that of ozone, and which appears to be due to persulphuric anhydride. When warmed with concentrated nitric or sulphuric acids the oxygen is liberated largely in the form of ozone. With hydrochloric acid chlorine is evolved. The ammonium salt NH_4SO_4 has been prepared in a similar manner; it crystallizes in long prisms and much resembles the potassium salt. The barium salt crystallizes in beautiful large interlocking prisms containing four molecules of water of crystallization.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. J. Barratt Lennard; a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Miss Corrie Chisholm; two Common Marmosets (*Hapale jacchus*) from South-east Brazil, presented by Mrs. Frederick Betts; two Bernicle Geese (*Bernicla leucopsis*), two Brent Geese (*Bernicla brenta*), European, presented by Mr. Cecil Smith; a Gamet (*Sula bassana*), British, presented by Dr. Davis; eleven Gold Pheasants (*Thaumalea picta* ♂s), two Amherst Pheasants (*Thaumalea amherstiæ* ♂ ♂), two Silver Pheasants (*Euplocamus nycthemerus* ♂ ♀) from China, a Common Pheasant (*Phasianus colchius* ♂), British, four Ruddy Sheldrakes (*Tadorna casarca*), European, presented by Mr. Edwin J. Poyser; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. F. Manners; a Macaque Monkey (*Macacus cynomolgus*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

MEASUREMENTS OF LUNAR RADIANT HEAT.—Numerous measurements of lunar radiant heat have been made at Birr Castle Observatory by Lord Rosse and Dr. Copeland, and the results obtained have been published from time to time. During the total lunar eclipse of October 4, 1884, Dr. Otto Boeddicker, Lord Rosse's present assistant, carried out a series of observations for the purpose of testing the striking result previously arrived at by Dr. Copeland, viz., that "the maximum of heat seemed to occur somewhat before full moon." It was then found that "The heat as before diminished, and increased again nearly proportionally to the light, becoming inappreciable on reaching the limits of totality. The minimum of heat apparently fell later than that of illumination. But the most remarkable thing was that while during the short interval between the first contact with the penumbra and the commencement of total phase, all appreciable radiation vanished, between the end of total phase and the last contact with the penumbra, and even forty minutes later, the heat had not returned to the standard for full moon, being deficient by about 12 per cent." These facts are remarked upon by Lord Rosse in an introduction to a paper by Dr. Boeddicker, giving the results obtained during the lunar eclipse of January 28, 1888 (Transactions of the Royal Dublin Society, Series III., vol. iv., Part ix., 1891). The measurements of radiation were commenced about an hour before the first contact with the penumbra, and a decrease of heat seems even then to have set in. But excluding this diminution of heat exhibited by the curve connecting the observations, there is indisputable evidence that the decrease had definitely commenced about three minutes before the eclipse began, and probably fifteen minutes before. This indicates, therefore, that the terrestrial atmosphere extends to a height of not less than 190 miles, and intercepts the sun's rays before any part of the moon has entered the earth's shadow. In 1888, as in 1884, the anomaly of the heat not returning to its standard value even 1 hour 40 minutes after the last contact with the penumbra, was observed. Dr. Boeddicker enumerates the series of observations required to elucidate these interesting points, and hopes soon to publish some further results of his investigations.

Two New Variable Stars.—The Rev. T. E. Espin has found two new variable stars in Cygnus, viz. D.M. + 36°·3852 and D.M. + 49°·3239. They are both of a strong red colour. The first has a Type III. (Group II.) spectrum, and the second belongs to Type IV. (Group VI.).

A New Asteroid.—The asteroid observed by Dr. Palisa on August 12 turns out to be Medusa (149), as was suggested by Dr. Berberich. On this account, the asteroids from (313) to (318) must be numbered from (312) to (317), and the one discovered on September 24 by Charlois will be (318).

A New Comet.—A bright comet was discovered on October 2, by Mr. E. E. Barnard, at Lick Observatory, in R.A. 7h. 31m. 24s., and Decl. − 27° 54′. It was moving to the south-east.

THE IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held on Tuesday the 6th inst. and Wednesday the 7th inst., under the presidency of Sir Frederick Abel. After the excitement of last year's meeting in the United States, the gathering of last week fell rather flat. As our readers are aware, it is the custom of this Society to hold two meetings each year—the first, in the spring, being in London, and the second, in the autumn, either in the provinces or abroad. This year it was proposed that Birmingham should be the place of meeting, but the great town of the Midlands does not appear to have responded to the overtures made, and, no other invitation being forthcoming, the Council was thrown back on the metropolis. In one point, at any rate, the meeting was a success, as on Tuesday a larger number of members travelled down to Woolwich, where a visit had been arranged to the Royal Arsenal, than perhaps have ever been got together before on an excursion.

The excursions are generally the leading feature of the autumn meetings, but there was but one organized for the meeting just past—namely, that to Woolwich Arsenal. The following is a list of the papers read:—On the constitution of ordnance factories, by Dr. William Anderson, F.R.S., Director-General of Ordnance Factories; on the measuring instruments used in the proof of guns and ammunition at the Royal Arsenal, Woolwich, by Captain Holden, R.A., Proof Officer at Woolwich; on the manufacture of continuous sheets of malleable iron and steel direct from fluid metal, by Sir Henry Bessemer, F.R.S.; on illustrations of progress in material for shipbuilding and engineering in the Royal Naval Exhibition, by W. H. White, C.B., Chief Constructor; on the forging press, by W. D. Allen, Sheffield; on an undescribed phenomenon in the fusion of mild steel, by F. J. R. Carulla, Derby; on the elimination of sulphur from pig-iron by J. Massenez, of Hoerde, Germany; on the Metallurgic Department, Sheffield Technical School, by B. H. Thwaite, Liverpool.

The first two papers were read at the Literary Institute, Woolwich. Dr. Anderson's contribution was taken first. It is a curious fact that the Director-General of Ordnance Factories, whose admirers used to claim, before he occupied his present position, that he was too scientific to be a successful business man, should have contributed what is perhaps the least scientific paper to be found within the Transactions of the Institute. The paper was what its title indicated, strictly a description of the constitution of the Royal Ordnance Factories. It told how they comprise the Laboratory, Gun Factory, and Carriage Department at Woolwich, the Gunpowder Factory at Waltham Abbey, and the Small Arms Factories at Enfield Lock and Birmingham. These establishments are, the author said, "supposed" to be worked on commercial principles. Dr. Anderson is an accurate and careful man, as has been proved by much good scientific work in the field of mechanical engineering which he has done, and there is much virtue in his "supposed." If ever a manufacturing establishment were worked with a view to profit after the manner of Woolwich Arsenal, the profits probably would be very small. The paper tells us that £400,000 is invested in stores, £557,945 in buildings, and £718,949 in machinery. By far the larger part of the work is done on the piece, or on the fellowship system. The number of hands employed is about 17,000, of which 13,000 are at Woolwich. In the financial year 1889-90, the value of completed work issued amounted to £2,259,126. The expenditure on all services, complete and incomplete, was £2,590,053, of which wages were responsible for £1,339,045, and materials for £1,005,224. The average wage earned per week per man and boy is 32*s.*, and about £19,000 a year is spent in medical attendance, which the men receive free.

Captain Holden's paper was on an interesting subject, but was far too brief to treat it in anything approaching an adequate manner. In addition to which illustrations are necessary to make clear the working of the various delicate instruments used in the measurement of the velocity of projectiles, but no wall diagrams were exhibited. It is true that some of the actual machines were shown, but these are a very poor substitute for sectional drawings, as one can see nothing but the outside. The Novez-Leurs chronoscope, Prof. Bashforth's chronograph, Schultz's revolving drum, together with the various modifications of it which have been introduced, were all briefly referred to. Most of these instruments are fairly well known, although not in general use. The Le Boulongé instrument, which is the one now universally used for determining the velocity of projectiles outside guns, was shown and its action illustrated. The author mentioned that when the Le Boulongé instrument was first introduced the highest normal muzzle velocities of guns were about 1000 feet per second. "Now," Captain Holden said, "they are double that amount; and it is probable they will reach 3000 feet per second." As an instance of the accuracy required in instruments of this nature, the author gave the following example: "The case of a shot whose mean velocity between two screens placed 180 feet apart is 1800 feet per second. A variation of one foot above or below 1800 feet per second is represented by a decrease or increase in time of only ·0005 of a second approximately." In order to work within such narrow limits the greatest care has to be taken to eliminate all sources of error in the instrument, and the precautions taken are briefly outlined in the paper.

After the reading of these two papers the members were conducted round the Arsenal, but such official wrath was threatened against any person who wrote for printing about anything he saw that we are too frightened to make further reference to this part of the proceedings.

On the second day of the meeting the members assembled at the Institution of Civil Engineers, Sir Frederick Abel, the President, again occupying the chair. The first paper taken was a contribution by Sir Henry Bessemer, in which he described an invention of his, devised nearly half a century ago. This consisted of the rolling of steel sheets direct from the molten metal as tapped from the furnace or converter. The process is simple in the extreme, and one can only marvel that the present complicated and costly methods should have stood so long, considering that Sir Henry Bessemer's patents have long since expired, and his direct process is open to anyone to adopt. The metal, as tapped from the furnace, in place of being run into ingots, to be afterwards rolled into slabs or billets, is just poured on to the top of a pair of water-cooled rolls placed with their axes in the same horizontal plane. The rolls are caused to revolve, and the molten metal finds its way down between the space left between them, and is thus rolled out into a continuous plate or sheet; the chill received in passing through the rolls being sufficient to solidify the metal. That the process is possible Sir Henry proved over forty years ago; that it may be made commercially successful appeared to be the unanimous opinion of the many competent critics who spoke in the discussion. Under these circumstances it would seem that the only reason why there should not be a radical change in the way of manufacturing steel plates is that the process is open to every one, and, as there are no patent rights to be acquired, it may be worth no one's while to go to the initial expenses of starting a new process just to show competitors how to do the same thing.

Mr. W. H. White's paper on the shipbuilding material at the Naval Exhibition was a useful and interesting contribution, although not so exhaustive as might have been desired. It would, however, be too much to expect so important a public servant as the Director of Naval Construction to devote his time to writing treatises for technical Societies. What Mr. White has written is of interest. He points out how the work of shipbuilding has been simplified and cheapened by the steel manufacturer, who now rolls many special sections, such as Z bars, channel bars, H bars, T bulbs, and angle bulbs, thus saving a vast amount of building up and riveting in the actual construction of the ship. The increase in the size of plates, both for ship and boiler work, was also pointed out by the author. Two specimens of boiler plate are shown in the Exhibition, which are both 1¼ in. thick and respectively 42 ft. long by 6¼ ft. wide, and 31 ft. long by 7½ ft. wide. Another way in which the steelmaker and founder has helped the shipbuilder is in producing complete parts of ships, such as stern frames and stems, especially the spur stems of war vessels, which necessarily have to be of massive construction. In old days, when such parts were made of wrought iron, the forging had to be machined to form the recesses or "rabbets" necessary for the attachment of plating. That was excessively costly work, and in the case of such heavy articles was most difficult to accomplish at all. With steel castings little or no machining is required. Mr. White exhibited a large hull diagram of a ram bow for a recent battle-ship. The part is made hollow, or rather recessed, and shelves are cast on to receive the plating of the decks, and the attachment of breast hooks, &c. The author also referred to the exhibits of armour plate made at the Exhibition, but the subject is too lengthy for us to go into here, excepting to say that nickel steel has been proved by test to show such good results for armour that some of the secondary armour plating for five first class battle-ships is now being made of that material.

Mr. W. D. Allen, in his paper, described a forging press, which, although it has been at work for some years at the Bessemer Works in Sheffield, is so ingenious, and so new to most people, that we shall attempt to describe it. The press has the appearance of a steam hammer, and, indeed, there is a steam cylinder at the top, just as in a hammer. The use of the steam, however, is only to raise the tup when the hydraulic pressure is released. The press consists of an anvil block below and a ram above, the work being in a vertical direction. The ram works in a hydraulic cylinder, and is carried through the top end of the latter in the shape of a stout shaft or shank, which may be described as a tail rod to the ram. Attached to this is the piston rod of the steam piston, the latter of course working in its own cylinder. The steam cylinder and hydraulic cylinder are therefore placed tandemwise, the latter being underneath. The hydraulic cylinder is supplied with water at pressure by a suitable pump, the barrel of the pump being in direct communication with the hydraulic cylinder, there being no valve of any kind between the two. If we have made our explanation clear, it will be seen that the ram will descend and ascend stroke for stroke with the pump plunger[1] (the same water flowing backwards and forwards continuously), it being remembered that the steam cylinder has always a tendency to lift the ram. Thus, upon the pump making a forward stroke, the water in its barrel is forced into the hydraulic cylinder; the ram is thus forced down, and gives the necessary squeeze to the work on the anvil. The pump plunger then starts on its return stroke, and so, by enlarging the space in the pump barrel, enables the hydraulic ram to rise and press the water out of the cylinder and back into the pump. The rising of the ram is caused by the lifting action of the steam under the piston; the latter, it will be remembered, being attached to the ram. Of course the water pressure is sufficient to overcome the steam pressure on the downward stroke. The chief use of this press is to produce work of any given thicknesses within the range of the machine. This end is attained by regulating the volume of water used. The action may be explained as follows. We will suppose, merely for simplicity sake,[1] the content of the pump barrel to be one cubic foot, and that of the hydraulic cylinder, when the ram is at the full extent of its stroke, to be two cubic feet. We will neglect the connecting pipe between the two, as that is not a variable and does not affect the principle. If there be admitted to the pump but one cubic foot of water as the plunger moves forward, it will drive all this water (omitting clearance) into the hydraulic cylinder, and the ram would therefore only descend one half its stroke. If the stroke were two feet the travel would be 12 inches, whilst there would be 12 inches of space between the anvil and the lower side of the squeezing tool on the end of the ram. Objects of 12 inches, or above 12 inches in thickness, could therefore be forged. If, however, an article 6 inches thick had to be worked, another half cubic foot of water would have to be admitted. As the pump barrel would only accommodate one cubic foot of water, the extra half cubic foot would remain permanently in the hydraulic cylinder, and the ram would therefore not go, by six inches, to the top of its stroke; in other words, the traverse of the ram would be carried six inches nearer the anvil. It will be remembered that the upward movement of the ram is effected by the steam cylinder, which is powerful enough to lift the dead weight of the ram, but is overcome by the hydraulic pressure. It will be seen that by regulating the volume of water in the machine, the ram—although always making the same length of stroke—can be kept working at any given distance from the anvil: the ram and pump-plunger making stroke for stroke as the water flows backwards and forwards between the barrel of the pump and hydraulic cylinder. The device is no less important than ingenious. In ordinary forging, reliance has to be placed for accuracy of work on the skill of the workman. It is surprising how near perfection a good forgeman will arrive by constant practice. Such men are necessarily scarce, and as a consequence very highly paid, but even the nearest approximation of eye and hastily applied callipers, with the chance of getting a little too much work on at the last minute, cannot equal the absolutely correct results of this automatic system. There is a very ingenious valve for regulating the admission of water to fine gradations, so as to get work accurately to gauge, but we have, perhaps, given enough description of mechanism for one article.

Mr. Carulla's paper was interesting and suggestive. He was engaged in melting Bessemer scrap in pots when a crucible gave way in the furnace just as fusion was nearly complete, the greater part of the contents flowing out into the fire. The melter was just bringing the crucible out, and, instead of finding an empty broken crucible in the tongs, he discovered a number of shells corresponding in shape with the pieces originally charged, but quite hollow. This was Mr. Carulla's unaccounted for phenomenon, upon which he invited an explanation. This discussion was not satisfactory, and it was evident that those who spoke had not prepared their ideas. This was not the fault of the speakers, but of the way in which the business of these meetings is carried on. The remark applies not only to the Iron and Steel Institute, but to most of the technical Societies of the same class. When a meeting is held, a mass of papers are brought forward and read more or less hurriedly, and members get up to make such remarks as may occur to them on the spur of the moment. It is needless to point out that no satisfactory discussion of matters involving scientific principles can be carried on in this way. Mr. Carulla's paper is, as we have said, suggestive, and a complete explanation of the facts he states would doubtless lead to most important discoveries in metallurgical science. In such cases as this we think it would be wise to read the paper and then postpone discussion until the next meeting; or, by preference, to have the paper printed in the Journal of Proceedings, and at a meeting subsequent to its appearance call for discussion. It would appear evident that the interior of the pieces of scrap had a lower melting-point than the exterior parts which formed the shells obtained, and the explanation of the variation in melting-point was the point requiring consideration. Liquation of the elements is naturally the first suggestion, but this only shifts the uncertainty, for liquation is itself an obscure matter. Mr. Snelus would explain the matter by decarbonization at the surface, which would render the interior parts more easily fusible. He had, in raking out a furnace, found pigs of which only the outer skin remained as metal, the case thus formed being filled with graphitic carbon. Mr. Galbraith attributed the phenomenon to the surface of the metal pieces having absorbed an infusible oxide when at a high temperature. There was, however, more in the circumstances described than the meeting was prepared to explain off hand, and it would be well if the discussion could be reopened at the spring meeting or brought on again by another paper.

---

[1] There are actually two plungers, the pump being of the duplex type; but this is a detail which does not affect the principle.

[1] The press ram makes a stroke of 2⅞ inches, and its diameter is 30 inches. The total pressure at 3 tons per square inch would be 1700 tons.

The contribution of Mr. Massenez was in many respects the most valuable of the meeting. It is a pleasing thing to see a foreign steelmaker putting his experience so unreservedly at the disposal of his English fellow-workers, and the thanks of the Institute are doubly due to the author for his valuable and practical paper. There is also an economic lesson in this matter, for the apparatus described owed its introduction to the German colliers' great strike of two years ago. Since then there has not only been a diminution in the amount of coal wrought, but the quality has also fallen off, so that the proportion of sulphur in the coal has much increased. This necessitated a desulphurization process, the method of which forms the subject of the paper. Manganiferous molten pig, poor in sulphur, is added to sulphuretted pig iron, poor in manganese; the result being that the metal is desulphurized, and a manganese sulphide slag is formed. The mixer in which the process is carried on is a large vessel in appearance, to judge by the drawings shown, like a converter. The apparatus in use at Hoerde will hold seventy tons of molten pig, but it has been shown that a vessel of about twice the size would be advisable. Details of the working are given by the author, and will be of great use to steelmakers working with phosphoric pig. In the discussion which followed several speakers bore testimony to the value of the invention, Sir Lowthian Bell intimating that a saving of 2*s*. 4*d*. per ton could be made by this method over the process of re-melting pig in the cupola; a step which has to be taken when it is desirable to combine the product of different blast furnaces. In the large mixer, metal from two or more furnaces can be brought together.

The only remaining paper was a contribution by Mr. B. Thwaite, in which particulars were given of the metallurgical department of the Sheffield Technical School, which was read in brief abstract by one of the clerical staff; after which the meeting was brought to a conclusion by the usual votes of thanks.

CARL WILHELM VON NÄGELI.

THE death of Carl Wilhelm von Nägeli, on May 10, 1891, removes the last survivor of that distinguished group of botanists who, side by side with zoologists such as Schwann and Kölliker, laid, half a century ago, the foundations of modern histology. The career of Nägeli is of special interest for the history of botany. During a period of fifty years he held a leading position in the advance of the science; and, while his activity began in the early days of Schleiden's predominance, his most recent work is in touch with those latest developments of biology which are connected with the name of Weismann. His work reached every side of the science. Systematic botany, morphology, anatomy, chemical and physical physiology, the theory of heredity and descent, as well as histology, all bear lasting traces of his influence.

Nägeli was born on March 27, 1817, at Kilchberg, near Zürich, and was the son of a country doctor. As a child he was devoted to books, but he soon showed a taste for natural history, which appears to have been in some degree inspired by his sister. His education as a boy was begun at a private school, of which his father was one of the founders, and was completed at the Zürich Gymnasium, where he did well. He then matriculated at the recently-established University of Zürich, with the view of studying medicine. As a student, he is said to have been strongly influenced by the "Naturphilosophie," as taught by Oken. He soon lost his taste for medical studies, and, owing to his mother's influence, was allowed to migrate to Geneva, where he devoted himself to the study of botany under De Candolle.

Nägeli took his doctor's degree at Zürich in 1840; his dissertation on the Swiss species of *Cirsium* was dedicated to Oswald Heer, and was his first contribution to that minute investigation of species which formed so characteristic a part of his life's work.

Subsequently Nägeli spent a short time at Berlin, studying, among other things, the philosophy of Hegel. A metaphysical tendency marks his writings all through life, and indeed favourably distinguishes his work from that of many less cultivated scientific writers; but Nägeli, in one of his later papers, expressly denies that he was ever himself an Hegelian.

Nägeli's next migration was to Jena, and here he came under the influence of Schleiden, by whom he was initiated into microscopic work. It was not long before the association of these two great men bore fruit. In 1844 appeared the first number of the *Zeitschrift für Wissenschaftliche Botanik* under the editorship of Schleiden and Nägeli. The connection of the former with the new venture was only a nominal one, and, indeed, all the papers but two are the work of Nägeli himself. The influence of Schleiden however, is manifest throughout, sometimes in an injurious degree, though the independence of Nägeli gradually asserted itself. To this brilliant, though short-lived publication we shall return presently. In 1845 Nägeli married, and on his wedding tour he spent a long time on the south-west coast of England, and there collected much material for his important work on "Die neueren Algen-systeme," published in 1847.

On his return to the Continent he became a *Privatdocent* at Zürich and lecturer at the veterinary school, and soon afterwards he was appointed Professor Extraordinarius. In 1850 his association with Cramer, so fruitful of good work, began. His colleague says of this time: "Es war eine schöne zeit! da wurden nicht bloss Staubfäden gezählt und Blattformen beschrieben; es ging in die Tiefe, ans Mark des Lebens!" It was the microscopic practical work with Nägeli which made the deepest impression on his distinguished pupil; his lectures, though clear and full of matter, do not appear to have been specially brilliant, but he possessed the highest qualification of a teacher in being himself a great maker of knowledge.

After declining a "call" to Giessen, Nägeli in 1852 became Professor at Freiburg im Breisgau, where most of the work was done for the "Pflanzenphysiologische Untersuchungen," published in conjunction with Cramer in 1855–58. In 1855 Nägeli accepted the post of Professor of General Botany in the new Polytechnic at Zürich; his work at this time was hindered by the temporary failure of his eyesight, owing to too much microscopic work.

In 1857 Nägeli was summoned to the Professorship of Botany at Münich, where King Maximilian II. was striving to render his capital as distinguished in science as it already was in art. This post Nägeli continued to hold to the time of his death. At first somewhat distracted from his original work by practical duties in connection with the organization of the institute and gardens, Nägeli soon resumed his proper activity, and continued for thirty years more to produce a magnificent series of researches on the most varied subjects. Unfortunately, Nägeli's work was excessive, and from the age of sixty onwards, his health began to suffer, so that he was ultimately compelled to give up teaching. An attack of influenza during the epidemic of 1889-90 seriously shattered his already failing strength, and from the effects of this he never completely recovered. He lived long enough to celebrate in great honour the jubilee of his doctor's degree, and thus to look back on half a century of continuous work for the advancement of science, a retrospect such as few savants can have enjoyed.[1]

Without attempting to give an adequate account of Nägeli's scientific work, a task which would far exceed both the limits of this article and the powers of the writer, some idea may be given of the salient points in his career as an investigator.

Nägeli's first histological paper, so far as we are aware, is on the development of pollen (1841). This already marks a decided advance on Schleiden's theory of free-cell formation, for Nägeli maintains that the special mother-cells are not formed directly around a cytoblast (nucleus) but around the whole granular contents, in the middle of which a free cytoblast lies. It was long, however, before Nägeli completely freed himself from the influence of Schleiden's histological theories. It is interesting that in this paper he described and clearly figured the two nuclei in the pollen-grain of an Œnothera, though he did not know that this was a constant phenomenon. The importance of this observation was not appreciated until Elfving, Strasburger, and Guignard, investigated the subject in our own day.

---

[1] The details of Nägeli's life are taken from the funeral address delivered by his colleague, Prof. Cramer, and published in the *Neue Zürcher Zeitung* for May 16, 1891.

Nägeli's "Botanische Beiträge" contributed to the volume of *Linnæa* for 1842, include some important papers. In those on the development of stomata and on cell-formation in the root-apex, he endeavoured to reconcile his own accurate observations with Schleidenian theories, and was thus led to oppose Unger, who had already recognized that vegetative cell-formation is a process of division. A paper on Fungi in the interior of cells is interesting, because the existence of such endophytic forms was at that time regarded as establishing a presumption in favour of spontaneous generation.

The *Zeitschrift für Wissenschaftliche Botanik*, 1844–46, is a very remarkable publication. It never got beyond its first volume, but it may be doubted whether any book of its size has been more important for the progress of the science. Nägeli's introductory paper, "Ueber die gegenwärtige Aufgabe der Naturgeschichte, insbesondere der Botanik," is very metaphysical in tone, and is not free from a certain youthful pedantry. Great stress is laid on the absolute difference of species—a conception which, as Nägeli tells us in one of his later works, did not prevent his believing even then in the origin of species by descent. The study of development is treated as a philosophical necessity, and anatomy, or the study of *mature* structure, is denied to be a science. This is perfectly just; no one did more for anatomy than Nägeli himself, but he recognized that it only becomes scientific in union with development and physiology. He further insists that the knowledge of development as a whole is the only sound basis for classification—a principle which still remains to be carried out. The highest importance is attached to the cell theory, which was expected to do as much for botany and zoology as mathematics had done for physics, or atomic formulæ for chemistry—an expectation which cannot be regarded as unjustified. Nägeli severely criticized the theories then current, according to which cell-formation is a process of crystallization. Some of the most doubtful of his own later generalizations, however, were affected by the same source of error—namely, too great eagerness to find a simple physical explanation for biological phenomena.

Nägeli, in this paper, devotes much space to the distinctions between animals and plants. He decisively rejects the idea of a transition between the two kingdoms, on the ground that this would contradict the "Absolutheit der Begriffe"—an argument which now seems strangely out of place in natural science.

The whole paper is of great interest as showing the point of view from which biological questions were regarded at that time by a brilliant and philosophical naturalist just entering on his life's work.

The two papers in the *Zeitschrift*, on the nuclei, formation and growth of vegetable cells (1844 and 1846), are of the greatest importance to histology, finally establishing the constant occurrence of cell-division as the one mode of vegetative cell-formation. This conclusion was only reached in its completeness in the second of the two papers. Although Unger's and Mohl's views of the details of the process were in some respects the more correct, still Nägeli established the main facts of the division of the nucleus and of the cell on a broad basis of observation. These papers, as well as one on the utricular structures in the contents of cells (nuclei, nucleoli, chlorophyll granules, &c.) were translated by Henfrey for the Ray Society, to the great benefit of English students, as the writer of this article can testify.

In the same journal there are several algological papers, the most important of which is the complete and admirable account of *Caulerpa prolifera*, the extraordinary histological structure of which and its relationship to the other Siphoneæ Nägeli already thoroughly understood. It is interesting that in this paper he describes both the cell-wall and the cellulose rods as growing by apposition, a view to which we have now returned, owing to the observations of Strasburger and Noll, in opposition to Nägeli's own later theory of intussusception propounded in 1858.

The paper on *Delesseria hypoglossum* contains an elaborate account of the cell-divisions by which the thallus is built up. Nägeli here characteristically attributes great importance to the introduction of ideas of absolute mathematical form into physiology and systematic botany.

The discovery of spermatozoids in the Ferns is one of the most important recorded in this volume. The essential points in the structure and development of the antheridia are described rightly, and the movements of the spermatozoids very accurately traced. Nägeli calls attention to the nuclear reactions of the substance of the spermatozoids. He demonstrates the homology of these bodies with those of the mosses and Chara and of animals. Nägeli was at that time necessarily completely in the dark as to the relation of the spermatozoids to spore formation, for the archegonia and the process of fertilization were first discovered by Suminski four years later.

Among other papers of fundamental importance may be mentioned that on the growth of mosses, in which the apical cell-divisions and the development of the protonema are clearly made out; that on the growth of the stem in vascular plants, a work which laid the foundation of our knowledge of the distribution of vascular bundles, and that on the reproduction of the Rhizocarps. This last is especially interesting. It is directed, though very cautiously, against the Schleidenian theory of fertilization as applied to these plants. It is singular how this theory, according to which the end of the pollen-tube, after penetrating the embryo-sac, itself became the embryo, took possession of the minds of botanists at that time, and led sometimes to the strangest confusions, sometimes to a chance recognition of homologies, which could only be legitimately proved at a later period of research. In the case of the Rhizocarps, the Schleidenian theory assumed that these plants were really Phanerogams. Hence we find that he and Nägeli agree in calling their microspores pollen-grains, their microsporangia anthers, their macrospores embryo-sacs, and their macrosporangia ovules, a terminology which very nearly expresses our present view of their homologies as established by Hofmeister. Nägeli discovered the spermatozoids of these plants as well as the prothallus and archegonia, but he shows the greatest reserve in correcting Schleiden's extraordinary mistakes.

It is worth remarking that at this early period the homology of pollen-grains with spores was generally admitted, and at first we wonder how this true result could have been arrived at so prematurely. Here again the Schleidenian theory affords the explanation. The pollen-grain was regarded as a spore, which on germination produced the embryo-plant, not as do the spores of Cryptogams in the open air, but within the embryo-sac of the ovule. This conclusion was of course strengthened by a more legitimate argument drawn from a comparison of the mode of origin of pollen-grains and spores.

A less fortunate result of the same theory appears in a paper in the *Zeitschrift*, "Ueber das Wachstum und den Begriff des Blattes." Nägeli here erroneously attributes to the stem and its branches an endogenous origin. That this holds good for the *primary* axis, he proves by stating that it is derived from the pollen-grain, which itself arises endogenously within the anther!

We have dwelt long on this *Zeitschrift*, as it affords a remarkable insight into the state of botanical questions during the earlier part of the most brilliant period of progress which the science has known. The very name, *Journal for "Scientific" Botany*, is characteristic, expressing the somewhat arrogant claims of the enthusiastic naturalists of the new school of that day.

The next period in Nägeli's career is marked by the publication of two important algological works: "Die neueren Algensysteme und Versuch zur Begründung eines eigenen Systems der Algen und Florideen," 1847, and "Gattungen einzelliger Algen," 1849. It cannot be said that Nägeli was altogether happy in his generalizations on algological subjects, though his special work was often of the greatest value. At that time he included the Lichens among the Algæ and excluded the Florideæ. The Algæ in his sense were distinguished from the Fungi, not only by the presence of chlorophyll and starch, but also by the absence of spontaneous generation, while they differed from the Florideæ and all the higher plants in being destitute of sex. The Florideæ, on the other hand, he regarded as sexual and as closely allied to the Mosses. He recognized their antheridia as the male organs, but regarded the tetraspores as the product of a female organ, on account of their superficial resemblance to the spore-tetrads of the higher Cryptogams. The carpospores, which are the real sexual products, he regarded as gemmæ like those of *Marchantia*, with the *cups* of which he compared the cystocarps. Such views were excusable at that time, but Nägeli, as we shall see, adhered to them later on with excessive pertinacity.

Nägeli was perfectly acquainted with the conjugation of Desmids and Zygnemaceæ and imperfectly with the fertilization of Vaucheria, but he imagined that these processes were too inconstant to be regarded as sexual.

Nägeli was at that time much more successful in dealing with the vegetative organs of the Algæ, and he rightly protested against the generalization current down to our own day, that all Algae are destitute of leaves.

His conviction that the Algæ are without exception sexless led him in 1849 to reject Decaisne and Thuret's discovery of the spermatozoids of Fucus, which he regarded as spores. Of his later algological papers, the most important is that on the Ceramiaceæ, published in 1861. In this the procarpia and trichogynes, the true female organs, are described and accurately figured; but Nägeli failed to recognize their true nature, and still maintained his old view of the sexuality of the tetraspores. The whole credit of the discovery of the real state of the case thus belongs to the French botanists Thuret and Bornet.

The "Pflanzenphysiologische Untersuchungen" of Nägeli and Cramer (1855–8) contain among other papers of importance Nägeli's huge work on starch grains (about 600 quarto pages!), which is of great general value as embodying his views on the growth of starch and cell-wall by intussusception and on the molecular structure of organized bodies. For many years this micellar theory, as it was afterwards called, was regarded as Nägeli's greatest achievement. Sachs, in 1875, said in his "History of Botany": "Nägeli's molecular theory is the first successful attempt to apply mechanico-physical considerations to the explanation of the phenomena of organic life." More recent research has shown that this attempt, like its predecessors, was premature, and though Nägeli's ingenious and carefully elaborated hypotheses must still arouse our admiration, we can scarcely now regard them as having added much to our knowledge either of the growth or structure of organized bodies. The book on "Starch Grains," however, quite apart from theoretical considerations, will always remain a marvellous monument of research. It contains a vast mass of systematic and descriptive matter in addition to the speculations which have made it famous. The micellar theory was further developed in subsequent papers "on the behaviour of polarized light towards vegetable organisms" (1862); "on crystalloid protein bodies" (1862); and "on the internal structure of vegetable cell-membranes" (1864). It is presented in its perfected form in the important work on the microscope, published by Nägeli and Schwendener in 1877.

The papers in the "Physiologische Untersuchungen" bear the name of Nägeli or of Cramer respectively, but it appears that they mutually assisted each other throughout; hence it is not out of place to mention here Cramer's fine researches on the apical growth of Equisetum, which to this day serve as a model (rarely approached) for all such investigations.

No sooner were these investigations with Cramer completed than another great undertaking was commenced in the publication of the "Beiträge zur Wissenschaftlichen Botanik" (1858–68). This began with the great paper "On the Growth of Stem and Root in Vascular Plants and on the Arrangement of the Vascular Bundles." This is the most important of Nägeli's purely anatomical works, and is of the greatest permanent value. It is not too much to say that the bulk of our knowledge of the distribution of vascular tissues in plants still depends on this work. Other valuable papers in the "Beiträge" are those on the use of the polarizing microscope, on the growth in thickness of the Sapindaceæ (another ideal pattern of anatomical research), and on the origin and growth of roots, in which last Leitgeb cooperated. Until the quite recent work of Van Tieghem and Douliot, this was undoubtedly the most important investigation on the subject.

Among Nägeli's later works there are two which have had a lasting influence on our views as to the biology and physiology of the simplest plants. In "Die niederen Pilze" (1877) he treats of moulds, yeasts, and bacteria in relation to infectious diseases and hygiene. In this work an excessive scepticism is displayed as to the existence of definite species among the lowest organisms, such as bacteria. There is no longer any doubt that species are neither more nor less distinct among these simple beings than among the higher plants, but Nägeli did a real service in showing that each of these species may appear in a number of morphologically and physiologically different forms.

Nägeli's "Theorie der Gährung" (1879) demonstrated the relation between the processes of fermentation and respiration, and established the modern view of fermentation, according to which, to use the words of Prof. Vines, "living protoplasm, besides undergoing decomposition itself, can induce decomposition in certain substances which are brought within the sphere of its influence."

It remains to consider briefly an aspect of Nägeli's work, which is from some points of view the most interesting of all—namely, his relation to the theory of descent. The elaborate observations on variable species, especially in the genus *Hieracium*, which Nägeli carried on throughout his whole life, side by side with his histological and physiological work, specially qualified him to take up an independent position with reference to the problems of evolution.

In his paper "Die Entstehung und Begriff der naturhistorischen Art" (1865), Nägeli for the first time discusses this question in the light of Darwin's work. His belief, however, in the origin of species by descent was no new thing, but had been tacitly held by him throughout his whole scientific career, and had been definitely expressed in his paper on individuality in Nature, published in 1856. In his work of 1865 he gave an admirably clear exposition of natural selection, but was unable to accept it as affording a sufficient explanation of evolution. He believed that variation has a definite direction, always tending towards the greater complexity and perfection of the organism (Vervollkommnungstheorie). On this view the development of the race, like that of the individual, has a definite course assigned to it beforehand. He protests that there is nothing supernatural involved in this doctrine, and that it does not necessarily require *sudden* transformations. On this latter question, however, he speaks very uncertainly, and states that transitions between certain morphological types appear to be unthinkable and impossible. One seems to catch here an echo of his older teaching about the "Absolutheit der Begriffe."

The perfecting process, he says, knows no rest; hence all plants would have become Phanerogams by this time were it not that spontaneous generation takes place at all periods. Thus the flowering plants of our own day have, on this view, the longest family history, and trace their descent from the first-formed "Urzellen," while the vascular cryptogams had a somewhat later origin, and have, consequently, not had time to advance so far, the mosses again arose more recently still, and so on with all the groups of plants. According to this singular hypothesis, there is no actual blood relationship between the higher and lower forms of any one epoch. They have had a similar but not a common origin. This remarkable, but, as it seems to us, retrogressive theory was maintained by Nägeli to the close of his career.

But, whatever view may be taken of this speculation, it must be admitted that Nägeli saw clearly the great fact—since brought home to us by the works of Weismann and his school—that the causes of variability are internal to the organism. This important doctrine, based on original experiments and observations, is maintained in a paper entitled "Ueber den Einfluss äusserer Verhältnisse auf die Varietätenbildung im Pflanzenreiche" (1865). He shows that "the formation of the more or less constant varieties or races is not the consequence and the expression of external agencies, but is determined by internal causes"; while the modifications directly produced by external influences are inconstant, and do not give rise to varieties. We think it must be allowed that, on this essential point, Nägeli was at that time somewhat in advance of Darwin himself.

Other works of that period deal with the laws affecting the distribution of species, and with the phenomena of hybridization. In the "Theorie der Bastardbildung" (1866) the peculiarities of hybrids are explained as due to the favourable or unfavourable changes produced by crossing, in the internal coadaptation of the organs of the offspring.

A paper on the social origin of new species (1872) results in the conclusion that groups of new forms are likely to arise simultaneously, rather than isolated new species.

Finally, something must be said of the great work published in 1884, "Die mechanisch-physiologische Theorie der Abstammungslehre," which states at great length Nägeli's final conclusions as to evolution and heredity. The fundamental idea of this weighty work is the conception of the Idioplasm, namely, of a definite portion of the general protoplasm, to which alone is committed the transmission of hereditary characters. This idea, as Weismann points out, is a fruitful one, and will live, and is indeed incorporated in all recent theories of heredity. Nägeli's speculations, however, as to the details of the distribution and molecular structure of this idioplasm are of much more doubtful value, and rest on no firm basis of actual observation.

Nägeli rightly argues that the character of the fertilized egg must be determined by a minute amount of idioplasm and not by the cytoplasm generally, because the characters of the male and female parent are on the average equally represented in the offspring in spite of the enormous difference in the bulk of the cytoplasm of spermatozoid and ovum.

It was only, however, after the idioplasm had been identified by Weismann and Strasburger with a definite constituent of the nucleus that the theory acquired a positive basis.

Nägeli in the "Abstammungslehre" points out that fertilization can only consist in the direct union of solid idioplasmic bodies, and thus on theoretical grounds arrives at a conclusion which has been fully confirmed by the observations of Van Beneden, Strasburger, and Guignard. He also shows that while in the higher organisms idioplasm alone is necessarily transmitted from parents to offspring, in the increase of the lower plants and animals by division, the descendants acquire a share of the nutritive protoplasm also. Hence in the latter the conditions of culture may directly affect the descendants, as Nageli found in his observations on bacteria. These views are in essential agreement with those of Prof. Weismann on the continuity of the germ-plasm, as brought forward a year later, though on other points there is a wide divergence of opinion.

Nägeli insists in his preface to this book, that the subject of heredity can only be authoritatively treated by a physiologist, and he no doubt regarded his micellar theories as an important contribution to the question. In this his view is somewhat one-sided, and as a matter of fact all recent advance in our knowledge of the essential points in reproduction has come from the morphological side.

Nägeli's attitude towards the question of spontaneous generation is interesting. In his early days he had no doubts as to the spontaneous origin of many Fungi, and thought that this could be experimentally demonstrated. In 1865 he gave up the experimental evidence, but believed in the origin *de novo* at all epochs of simple vegetable cells. In the "Abstammungslehre" he still maintains that spontaneous generation is constantly in progress, but no longer holds that even the lowest known organisms can arise in this way. His supposed primitive living things (*Probien*) are as much more simple than bacteria, as these are more simple than the highest animals or plants.

As regards the causes of evolution, Nägeli in his great work appears to limit the field of natural selection even more narrowly than in his earlier essays. Its function, according to his later views, consists in the separation and definition of races by the elimination of ill-adapted forms, rather than in determining the origin of the races themselves. In a brilliant illustration he pictures natural selection as pruning the phylogenetic tree, though powerless to cause the putting forth of new branches. He still regards evolution as a necessary progress towards perfection determined by the constitution of the organism itself, and more especially of its idioplasm.

This view is only needed if we assume with Nägeli the existence of purely morphological characters—of characters, that is, which are not, and never have been, of the nature of adaptations. It appears to us to have been sufficiently shown by Prof. Weismann and others that the existence of such characters is an unnecessary assumption. As biology advances, we learn every day the function of characters which had before appeared to us to be useless, and the whole tendency of investigation is to prove that all characters whatsoever are either of direct use to their present possessors or have been inherited from ancestors, to whom, at the time when they were acquired, they were equally advantageous. It would be difficult to cite a stronger instance of a "morphological character" than the alternation of generations which so clearly characterizes the higher cryptogams. Yet it has been lately shown by Prof. Bower that this may well have been an adaptive character at its first origin, the sporophyte being adapted for taking possession of the dry land, while the oophyte, owing to the mode of fertilization, was compelled to retain a lowly and semi-aquatic habit.

We have given a very incomplete and imperfect sketch of the life-work of one of the most illustrious of that illustrious band of botanists to whom the chief advances of our science are due. Much of his work has of necessity been left quite unnoticed. But on even a cursory glance through the writings of Nägeli the conviction is forced upon us that he was a man not only of exceptionally wide scientific and philosophical training and of great literary power, but also one of real genius, and as far removed as possible from that narrow specialism which is the besetting sin of so much modern scientific effort. The judgment of Nägeli's colleague, Prof. Cramer, that he was "a truly great man," cannot be dismissed as the exaggerated language of personal affection, but expresses a truth. Though some of his theories may be abandoned, a vast sum of permanent achievement will always remain, and the influence of Nägeli on the future of our science will be powerful and lasting.

D. H. Scott.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—Full term commences on Saturday, October 17. The following lectures in science generally have been advertised:—

The Savilian Professor of Geometry (J. J. Sylvester) will lecture on surfaces of the second order, illustrated by the models with which that department has been supplied at the request of the Professor.

The Professor of Astronomy (Rev. C. Pritchard) proposes to lecture on the methods of determining astronomical constants, and offers practical instruction with the transit circle and solar spectroscope.

Rev. Bartholomew Price (Sedleian Professor of Natural Philosophy) lectures on hydromechanics.

The Professor of Experimental Philosophy (R. B. Clifton) will lecture on electricity; and instruction in practical physics is offered by Mr. Walker and Mr. Hatton at the Clarendon Laboratory. Lectures on mechanics and experimental physics are offered by Rev. F. J. Smith, at the Millard Laboratory.

The Waynflete Professor of Physiology (J. S. Burdon-Sanderson) will lecture on the subjects required for the final examination in the School of Physiology, and Mr. Dixey will lecture on histology. Practical instruction on this latter subject will be given by Mr. Kent.

In the subject of Chemistry, the Waynflete Professor (W. Odling) will lecture on animal products, while the Aldrichian Demonstrator (W. W. Fisher) will give a series of lectures on the non-metallic elements. Mr. J. Watts lectures on organic chemistry, and the instruction in practical work is under the supervision of Mr. Watts, Mr. Veley, and Mr. J. E. Marsh.

The Deputy Linacre Professor of Human and Comparative Anatomy (E. Ray Lankester) offers a course of lectures on comparative anatomy and embryology. This course is intended for seniors. There will also be a junior course for beginners and candidates for the preliminary examination in animal morphology conducted by the Deputy Linacre Professor and Dr. W. B. Benham. This last-named gentleman will also lecture on the Chætopoda.

The Professor of Geology (A. H. Green) offers two courses of lectures, one on physical, the other on stratigraphical geology.

The Reader in Anthropology (E. B. Tylor) will lecture on the origin and development of language and writing.

The Sherardian Professor of Botany (S. H. Vines) lectures, this term, on elementary botany.

The Hope Professor of Zoology (J. O. Westwood) lectures and gives informal information upon some of the orders of Arthropoda.

In the department of medicine, Sir H. W. Acland, Bart., gives informal instruction on modes of medical study. This instruction is given at the Museum, where arrangements will be made for one or more demonstrations in illustration of subjects bearing on public health. Dr. Collier and Mr. Morgan give demonstrations for the Professor on Medical and Surgical Pathology. The Lichfield Lecturer in Clinical Medicine (W. Tyrrell Brooks) will lecture on the physical signs of disease, and the Lecturer in Clinical Surgery (A. Winkfield) offers instruction on the treatment of fractures, &c.

The Lecturer in Human Anatomy (A. Thomson) offers a course of lectures on human osteology, and a series of demonstrations will be arranged to meet the requirements of those working in the department. The dissecting-room will be open daily for practical work and instruction.

The Rev. H. Boyd, Principal of Hertford College, has been nominated Vice-Chancellor for the ensuing year.

A mathematical fellowship has been awarded at Merton College to Mr. Arthur Lee Dixon, B.A., formerly scholar at Worcester College. Mr. Dixon was placed in the first class both at Moderations and in the final Mathematical Schools. He obtained the Junior Mathematical Scholarship in 1887 and the Senior Mathematical Scholarship in 1891. Also at Corpus Christi College a mathematical fellowship has been awarded to Mr. Arthur Ernest Jolliffe, scholar of Balliol College. Mr. Jolliffe was placed in the first class by the Mathematical Moderators in 1889, and in the first class by the Examiners in Scientiis mathematicis et physicis in 1891. He also obtained the Junior Mathematical Scholarship in 1889.

CAMBRIDGE.—The erection of the Newall telescope is nearly completed. Prof. Adams was able to use it for the first time last week, and took an observation of Neptune.

Prof. Ewing announces that the new Engineering Laboratory is ready for use, and will be occupied this term.

Mr. F. Blackman, of St. John's College, has been appointed Demonstrator of Botany.

By the return of Prof. Jebb, the University enjoys the distinction of being represented in Parliament by a Senior Classic (Dr. Jebb) and a Senior Wrangler (Sir G. G. Stokes).

Sixty-four candidates entered for the examination in sanitary science held last week. Of these forty-three have passed both parts of the examination, and receive the diploma in Public Health.

The Lecturer in Geography (Mr. Buchanan, F.R.S.) will this term lecture on physical and chemical geography, with especial reference to land surfaces and their development under climatic and other agencies.

The vote in the Senate on the question whether a syndicate shall be appointed to consider alternatives for Greek and Latin in the Previous Examination will be taken on Thursday, October 29, at 2 p.m.

University Extension.—It is announced that Mr. T. D. Galpin, of the firm of Cassell and Co., Limited, has offered to the Dorset County Council the sum of £1000 to be invested for the purpose of providing scholarships to send natives of Dorset to the Summer Meetings of Oxford and Cambridge. The scholarships will be awarded to the writers of the best essays, and it is proposed that the examination should be conducted by the University Extension Committee of the Oxford Delegates of Local Examinations. The scholarships are to be awarded without distinction of sex, or any political, sectarian, or social distinction whatever.

SCIENTIFIC SERIALS.

THE *American Journal of Science*, October 1891. Some of the possibilities of economic botany, by George Lincoln Goodale. This is the Presidential address delivered before the American Association for the Advancement of Science, at Washington in August last.—On the vitality of some annual plants, by T. Holm. The author enumerates several species of plants which show a tendency to vary from annual to biennial or perennial.—A method for the separation of antimony from arsenic by the simultaneous action of hydrochloric and hydriodic acids, by F. A. Gooch and E. W. Danner.—Notes on allotropic silver, by M. Carey Lea. The blue form of allotropic silver is mainly considered. The action of light on this form is remarkable, for its effect is first to increase the sensitiveness to reagents and then to completely destroy it. This reversing action is analogous to that which light exerts upon silver bromide. Mr. Lea has also examined the point as to whether in the reduction of silver, the allotropic or the normal form is produced, and he finds that when the silver passes from the condition of the normal salt or oxide to that of the metal, the reduced silver always appears in the ordinary form. But when the change is first to sub-oxide or to a corresponding sub-salt, the silver presents itself in one of its allotropic states.—Structural geology of Steep Rock Lake, Ontario, by Henry Lloyd Smyth.—On the so-called amber of Cedar Lake, North Saskatchewan, Canada, by B. J. Harrington. The resin or "retinite" examined by the author had a hardness of about 2·5, and a specific gravity 1·055 at 20° C. An analysis gave for its composition, carbon 80·03, hydrogen 10·47, and oxygen 9·50.—Geological horizons as determined by vertebrate fossils, by O. C. Marsh. The method of defining geological horizons by vertebrate fossils was first used by the author in 1877, and appears to afford the most reliable evidence of climatic and other geological changes. It is now extended and revised. A section accompanies the paper representing, in their geological order, the successive strata at present known with certainty from characteristic vertebrate fossils.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 3.—M. Duchartre in the chair.—On the variations of composition of Jerusalem artichokes from the point of view of mineral matters, by M. C. Lechartier. The author gives the results of some investigations made at the Rennes Agricultural Station, on the culture of artichokes in soils differently treated. He has also studied atmospheric influences as indicated by cultures on similar plots for three consecutive years.—Observations of Wolf's comet made with the great telescope of Toulouse Observatory, by M. E. Cosserat. Observations for position were made and are recorded, extending from August 13 to September 28.—On the value of electrostatic tension in a dielectric, by M. L. de la Rive.—On the simultaneous existence, in cultures of *Staphylocoque pyogène*, of a vaccine substance capable of being precipitated by alcohol, and of a substance soluble in alcohol, by MM. A. Rodet and J. Courmont.—On some parasite Copepods, by M. Eugène Canu.—Observations of the fall of a solar prominence into a spot, by M. E. L. Trouvelot. The observations relate to some remarkable luminous filaments occurring in a group of spots from August 6 to August 10.

THURSDAY, OCTOBER 22, 1891.

RUDOLF VIRCHOW AND HIS COUNTRYMEN.

THE German people are to be congratulated on the brilliant way in which the seventieth birthday of Prof. Virchow was celebrated last week in Berlin. We say the German people, because the entire nation associated itself with the scientific societies in doing honour to the illustrious investigator of whose achievements it has for many a day been so justly proud. Everyone who devotes the slightest attention to science is aware that Prof. Virchow occupies a prominent place among the foremost intellectual leaders of the present age. As the *Times* has said, "So much has he done, and so thoroughly has he done it, that it is difficult for this generation to apprehend the full magnitude of his work. Open a book on medicine, and especially any volume on pathology, composed, it matters not much where, before Virchow began his observations, and compare it with one composed with the light of his endless investigations to guide the author: a veritable revolution in conceptions and terminology has taken place; at every turn you read, 'All this is understood since Virchow wrote,' or words to that effect; and you are referred to his multifarious 'epoch-making' articles scattered through many professional and technical periodicals." By his great principle, "Omnis cellula ex cellula," he made a contribution of the highest importance to biological science; and his conception of cellular processes introduced wholly new and most fertile ideas as to all the phenomena of disease. The science of pathology as it is now understood and taught we owe, indeed, mainly to his insight and labour, and the recent advances which have been made in it by other explorers have been made on the lines he has traced. If Prof. Virchow had done nothing else for science, this alone would have secured for him imperishable fame; but his energies are so varied that it has been impossible for him to content himself with one department of research. As a student of archæology, ethnology, and anthropology, he is hardly less eminent than as a pathologist. In all these sciences he has marked an era by his writings, and by the personal influence he has exerted on the Berlin Gesellschaft für Anthropologie, Ethnologie, und Urgeschichte, which he founded in 1869. In practical life, too, as a member of Parliament and of the Municipal Council of Berlin, Prof. Virchow long ago made himself a great power in Germany. He has missed no opportunity of expounding the laws of public health, and of insisting upon their importance; and a striking testimony to the value of his work in this direction may be seen in the improved sanitary condition of the German capital.

To the Germans it seemed perfectly natural that, when so illustrious a man of science completed his seventieth year, the nation should offer its congratulations on the splendid results he had accomplished. Would an English man of science of corresponding intellectual rank have received similar tokens of popular gratitude and respect? Unfortunately, the question answers itself; and it would be well worth the while of Englishmen to consider carefully the causes which have led to the contrast in this respect between them and their German kinsfolk. It may be said that Germans are more demonstrative than Englishmen, but this by no means accounts for the very different ways in which scientific discoverers are treated in the two countries. The real root of the difference lies in the fact that the importance of science is much more highly estimated in Germany than in England, and especially by the Governments. For several generations, the various German Governments have done everything in their power to foster scientific investigation. With this object in view, they have spent money freely and wisely, allowing themelves to be guided, not by impulse or caprice, but by the advice of men of wide experience and knowledge. They were quick to note the influence which might be exerted on industrial development by technical education; and the result is that Germany has for some time had as many technical schools and colleges, adequately equipped, as are necessary for her wants. We need scarcely say how very different is the spirit that has hitherto animated our own Government. The idea of most English statesmen about science seems to be that it is a bore and a nuisance, and that the less they have to do with it the better for themselves and the public. Even for technical instruction they declined to make provision, until, by an accident, the present Government found itself in possession of a fund which it did not know how to get rid of except by giving the County Councils authority to use it for the establishment of technical schools and classes. Is it surprising that when their rulers act in this way the mass of the British people should be utterly indifferent to scientific progress? The Germans have been accustomed all their lives to see science encouraged, and all classes learn therefore to regard it as an essential factor in the evolution of their national life. This week they have had a fresh example of the respect in which science is held, the Emperor having appointed Prof. Helmholtz a member of the Privy Council, with the title of Excellency. In the telegram announcing to Prof. Helmholtz the honour conferred on him, the Emperor took occasion to refer with pride to the lustre shed on Germany by his scientific achievements. Nothing of the kind is ever done here.

The influence of education must also, of course, be taken into account. There is still some dispute in Germany, as in other countries, about the exact place which properly belongs to science in general education; but there is no dispute at all as to the importance of training children to recognize the benefits which science in all its branches has conferred on mankind. Moreover in the "Realschulen" an excellent scientific training is provided for those who either have little power of appreciating classical literature, or who are likely to be best fitted for their future work by the study of science. And in elementary schools an effort is everywhere made to interest children in the facts and laws of nature, and to give them some conception of the objects and methods of scientific inquiry. How far we lag behind the Germans in these respects all true "educationists" know. We have made only a beginning in the use of science as an instrument of popular culture, and many years, we fear, may pass before we shall have applied it sufficiently to render scientific conceptions a really vital element in the intellectual life of the community.

It is not for the sake of men of science that we desire to see more widely diffused an intelligent appreciation of their work. A celebration like that of last week necessarily brings with it sad as well as happy reflections. "After all," said Bluntschli, the famous jurist, on a like occasion, "it is an end, not a beginning." Prof. Virchow is fresh and vigorous, and the world may still reasonably expect from him much sound work; but we may be sure that, in responding to congratulations, he had a little of Bluntschli's feeling; and it is possible that, if he had consulted his own wishes only, he would have preferred to celebrate his seventieth birthday more quietly. But it is good for a nation to express on such occasions the admiration and reverence excited by a long and great career. The mere fact that men desire to honour one whose title to distinction is that he has advanced human knowledge proves that they have interests higher than those of a material character; and it inevitably tends to deepen and strengthen the best and most enduring of their impulses. We should be glad, therefore, if Englishmen had as strong a wish as Germans to display a hearty appreciation of the triumphs achieved by their great scientific thinkers. That would be the most effectual of all proofs that they had begun, as a people, to understand how momentous is the part which science has played, and must continue to play, in the modern world.

ELECTRIC LIGHT FITTING—GOOD AND BAD WORK.

Electric Light Fitting: a Hand-book for Working Electrical Engineers. By John W. Urquhart. (London: Crosby Lockwood and Son, 1890.)

THIS book is exactly what it professes to be—a practical book for practical men—and is vastly superior to "Electric Light," by the same author. The detailed instructions given in the first 42 pages, on the erecting, managing, and repairing dynamos, are admirable, and are not to be found in any other book in the English language. The young electrical engineer will find just the information he needs: how to fit up a large dynamo when received in parts from the makers; how to prevent the commutator becoming rough in use; exactly what to do if it be rough; how to prevent sparking at the brushes; how to attach a new commutator and make joints in the armature wires; what to do if the dynamo heats; and how to get over the various other difficulties met with in the dynamo-room.

The author, in these early chapters, and indeed throughout the book, uses the expression "constant current" for direct current; and although the action of the regulators of the Brush and of the Thomson-Houston constant current dynamos is correctly described, and clear illustrations given of their construction, the reader is left in the dark as to the exact use of these regulators. Or, rather, the only definite statement as to the function of the Thomson-Houston regulator, that it is "for causing the machine to evolve more or less current as required," is certainly much more likely to lead the reader wrong than right. Further, to say that "in Siemens's alternator, or the Ferranti dynamo, 'lead' must be given to the brushes" (an instruction, of course, quite impossible to carry out, as alternate machines have no commutators, but only collecting rings), will probably destroy the correct impression about lead which the practical man may have derived from reading the previous page.

In spite of these defects, however, chapter i. is excellent, but we cannot speak quite as highly of chapter ii., "On Localizing Dynamo Faults, and Observations respecting Accumulators." In describing the test for the existence of leakage between the iron framework and the earth, the author makes an error that we have met with before, in stating that a deflection of a galvanometer whose ends are connected respectively with the iron framework and the earth indicates leakage between these two. This is equivalent to saying that a conductor not having the potential of the earth proves that it is in connection with the earth. In the "Hints to Accumulator Attendants" there are some very useful suggestions, but the instructions for deciding when an accumulator is charged confirm the impression we gave when reviewing the author's "Electric Light," that the author had not derived his knowledge of storage cells from a practical acquaintance with them. For he says that they must not be so much discharged that they cease to give any current; and in the chapter on "Switch Board and Testing Work," that the E.M.F. of accumulators, in discharging, should never be allowed to fall below 0·5 volt per cell. Such instructions are about as useful as saying that a horse should not be worked until he dropped, for if accumulators were to be regularly discharged until their E.M.F. fell to a value even three times as great as the limit prescribed by Mr. Urquhart, they would be speedily ruined.

Why these two statements about the discharge limit of storage cells should be given in different parts of the book, with information about "Running Dynamos in Parallel," the "Periodicity of Alternators," &c., inserted between, we do not know. In a somewhat similar way, the author returns again and again in different parts of the book to the subject of insulation resistance. Each time, no doubt, valuable information is given; but why not have put it all together, so that the working electrical engineer could have at once read up the subject, without having to turn up a number of references? This sort of scattering of information runs through the whole book, and rather suggests the idea that no very serious attempt was made to sort out information written down by the author as it occurred to him at different times.

We do not think that the explanation on p. 54. "alternators work according to a 'phase,'" is very lucid, Further on, the author says the number of phases per second is the periodicity, and later that periodicity and phase are the same thing. On p. 51 we are told "a fall of five volts in a hundred affects the brightness of the lamps," from which a person might easily obtain the wrong impression that a fall of two or three per cent. was not observable, and be astonished when he read, on p. 72, "that a fall of five volts in a hundred in the working pressure will cause lamps which burn brightly at a hundred volts to become very dull." He would also not be able to reconcile the statement, "upon well-conducted systems the pressure upon the mains is never allowed to vary more than one-half per cent.," with the variation of 2 per cent. up and 2 per cent. down, which is allowed by the Board of Trade. Nor is it possible to understand the rule with reference to the wiring of a house, "It should show an insulation resistance of at least ·1 megohm per lamp," since this would make the insulation of an installation the higher the greater the number of lampholders, whereas of course, as a matter of fact, the very reverse is the case.

Chapter iv., on "Arc Light Wiring and Fitting," is full of practical suggestions; the instructions on the trimming of arc lamps, and the precautions that ought to be adopted in order to keep arc lamps in good working order, will greatly help the young engineer when he is first put in charge of arc lamps. It is a pity, however, that when the author is speaking of supplying constant current to a variable number of arc lamps running in series, he should say, "but the shunt or compound-wound machines are supposed to regulate themselves, which they very often fail to do." For we never heard of a compound-wound machine, still less of a well-made shunt machine, which professed to produce a constant current when the external resistance was varied. And this mistake is emphasized in the next section, on running arc lamps in parallel, since, although it is quite rightly said of the attendant, that "his chief care is to keep the *potential difference* between the leads the same," Mr. Urquhart states, "This is usually effected in part by the dynamo itself when a shunt-wound machine is used, or by regulating the speed"; and he makes no reference here to the use of a compound-wound machine, as if it were not the special function of this type of machine to keep the potential difference between the mains constant.

There is a good illustration on p. 107 of the Thomson-Houston lightning arrester, with an explanation of its construction, but no hint is given that the electric arc produced by the lightning flash is magnetically blown out and thus extinguished. And in the large perspective illustration of a Thomson-Houston transformer, given in this chapter, the thickly-insulated leads are shown with a thick copper conductor inside them, while the lightly-insulated leads have a thin conductor, and since, in the description of a transformer, it is not stated that, besides transforming from a high to a low *potential difference*, this apparatus also transforms from a small to a large *current*, it would be quite possible for a beginner to read this book, and wonder why people went out of their way to construct dynamos to produce one or two thousand volts, and then had to employ special apparatus at the consumers' premises to lower this high potential difference. "It is usual to put the secondary circuit to earth," probably expresses the author's view (as it also does the reviewer's) of the proper way to guard against accidents being produced by a contact between the primary and secondary circuits of a transformer, but it certainly does not represent the ordinary practice.

The name "impedance coils" is suggested for inductive coils used to diminish a varying or an alternating current; but the necessity for this name arises from the expression "choking coils," which is commonly used in this sense, having been wrongly employed by the author for any kind of resistance coils, such as, for example, a non-inductive resistance used with a steady current.

Chapter v., on "Wiring for Incandescent Lamps," abounds in useful hints, and is illustrated with several well-executed woodcuts. Admirable, however, as may be the switches, fuses, &c., constructed by Messrs. Woodhouse and Rawson, the succession of illustrations with the names of that firm underneath tends to give the impression that there are no other manufacturers of such apparatus. Surely the weighted fuses made by the Acme Works, the switches of Messrs. Siemens—which provide a metallic circuit for the current but expend the flash, produced by opening the circuit, on carbon contacts—and the S switches of Messrs. Crompton, were worthy of a reference.

If the well thought out precautions detailed in "Methods for Running Wires" had been followed in all the wiring of houses that has been carried out during the past few years, we should not have heard of those very justifiable complaints of occupiers who, after taking the lease of a house, temptingly described in the agent's list as fitted throughout with the electric light, find that they have to entirely re-wire the house before the insurance office will allow the current to be turned on. We thoroughly agree with the author that "There is one leading maxim for a contractor putting in electric light, and it is to avoid contracts that do not allow of the best class of material and labour being used throughout." We should also like to impress on the general public that the plummer, or the carpenter's handy man, is not, as they seem to think he is, any more capable of fitting up an electric installation than he is of setting a broken leg.

We do not understand why, as a definition of "cleat wiring," Mr. Urquhart says, "This means uncovered wires run &c."; surely cleats are frequently employed to hold down covered as well as uncovered wires. On p. 185 the temperature is not stated at which "the ohm is the resistance offered by a column of mercury 1 square millimetre in cross-section and 106 centimetres long." Power and work are said to be synonymous, and foot-pounds said to be analogous with volt-amperes. The output of 1000 watts "is called under the Board of Trade regulation a *kilowatt*," whereas the late Sir William Siemens, and not the Board of Trade, originated this name. "As lamps are now made, each would probably give a light of 20 candle-power, the watts per candle-power being 2·5." Would that we could buy glow lamps which had a decent life, while needing only 2·5 watts per candle.

Sir William Thomson's rule about the right sectional area to give to a conductor "is only a suggestion made for the protection of buildings from fire." We thought everyone knew that it was a rule for settling the thickness of the conductor with which maximum economy could be obtained.

The rules about jointing leads are exact and valuable; we do not, however, like the general rule of using the body of a chandelier itself to serve as the return, and we think this rule ought to be followed only when the return wire is throughout the installation an uninsulated one.

Chapter vi. gives a good *résumé* of the *pros* and *cons* regarding the use of the body of an iron ship as the return for ship lighting; while chapter vii. gives the substance of the rules issued by the Institution of Electrical Engineers, in connection with fire risks and danger to life.

MORE SUGGESTIONS FOR COUNTY COUNCILS.

County Councils and Technical Education. By J. C. Buckmaster. (London: Blackie and Sons.)

UNDER the above title Mr. Buckmaster, who for many years has been connected as teacher, lecturer, and organizer with the Science and Art Department, gives some statistics relating to technical education, and his views on the best way of utilizing the funds in the hands of County Councils. We need hardly say that, backed as they are by so long an experience, his opinions deserve the most careful and respectful consideration.

Briefly stated, Mr. Buckmaster believes in class teaching as opposed to lectures, and in utilizing as far as possible existing elementary and science and art teachers. "Unless," he says, "the sympathy of teachers and other educationists can be enlisted, the most carefully considered schemes of County Councils can only end in partial or complete failure." Again,

> "Lectures by themselves are never to be highly valued as a means of education. In a lecture on science, to create and sustain an interest, you must be popular, and to do this you avoid the complex difficulties of the science, which are often the only intellectual parts of it. . . . Lectures, unless followed up by thought and reading on the part of those who hear them, fail as a means of education, &c., &c."

All this is excellent, and the warning is useful. But when Mr. Buckmaster comes to the application of these principles he is not quite so happy. For example, he is unjust to the University Extension system, which he does not clearly understand, and treats as though it were mere popular lecturing, like the work of the old Mechanics' Institutes. Now, though we have no belief that the University Extension machinery can fill the place of elementary class teaching, we cannot accept the implied suggestion that courses of ten or twelve lectures (often arranged in sequences of two or three sets of twelve lectures), each lecture followed by a class for the more serious students, and by written paper work corrected by the lecturer, and the whole course tested by independent examination, form an engine of instruction scarcely above the level of a clever conjuror's performance.

His constructive suggestions are, first, to use elementary teachers to give object-lessons in simple science—a most useful proposal, about to be carried out in various counties as soon as the teachers themselves can be properly trained for the work; and secondly, to multiply science and art classes. "The best technical instruction for some time will be a wider development and extension of the educational work of the Science and Art Department by means of night classes and continuation science and art schools." This depends, of course, on the meaning to be attached to "development." If it merely means multiplication, the statement is open to serious question. No one can know better than Mr. Buckmaster the special dangers attaching to the system which he advocates—the abuses which grow up round a system which makes the financial success of the class, and usually the salary of the teacher, depend on the result of an examination. In our opinion, the machinery of the Science and Art Department will long continue to be a most useful and important factor (though not to the exclusion of other agencies) in the development of technical instruction. But the present is the great chance to consolidate and improve, rather than merely extend the work. If the County Council funds are so granted as to correct the evils which inevitably arise out of such a system of payments on results as is adopted by the Department—if its control is used to render more effective the ***inspection*** as opposed to the mere examination of science and art classes—then the portion of the grant given to promote the work aided by the Science and Art Department will be well spent. But no claim on the part of this or any other single agency to a monopoly of all technical instruction above the rank of that which can be given by the village teacher can be conceded. Mr. Buckmaster does not in so many words make the claim, but he sometimes seems to imply it by minimizing the value of most other experiments which County Councils are attempting. It is virtually a plea for educational bureaucracy against local experiment. But we have not yet reached the stage, if, indeed, we ever do so, when variety of experiment can be dispensed with. Some of the experiments will probably fail. But it is only by wide and free experimenting that the "fittest" will be discovered. Mr. Buckmaster has confined himself, probably on purpose, to the elementary branches of technical instruction, and is silent on its higher developments. Manual work he only just mentions, and not with much sympathy. His criticisms on the wood-carving taught by ladies in villages is not, perhaps, too severe; but it is strange that he does not give a hint that systematic manual training may be (as it has been for a long time in other countries, and lately in our own) made of real educational value. Not a word is said of the worst defect of all in our educational system—the want of good, cheap, secondary schools, which the present grant may do so much to remedy.

Though, however, Mr. Buckmaster takes a rather cramped and narrow view of the outlook, his pamphlet is full of valuable, if rather partial, ideas.

The pamphlet opens and concludes with some useful statistical and other information taken from various publications of the National Association for the Promotion of Technical and Secondary Education. Readers who do not know the source from which these pages are derived may be puzzled by a reference to "the Committee" (p. 41), which by some error in editing has been left still standing, without explanation, in Mr. Buckmaster's pamphlet.

THE MISSOURI BOTANICAL GARDEN.

Missouri Botanical Garden: Second Annual Report. By William Trelease. Pp. 188; Plates 48, reproduced Photographs 5, and Plan of Garden. (St. Louis, Missouri: Published by the Board of Trustees, 1891.)

THE Board of Trustees of the Missouri Botanical Garden have instructed the Director to edit for publication each year a volume setting forth the objects of the Garden and the School of Botany, and the results accomplished by each. The first volume of this series was issued in December 1890, and contained an account of the Garden and School. The present volume, therefore, really begins the series of annual reports, and together with the reports we have a revision of the North American species of *Epilobium*. In the earlier part of the book details are given of the appointment of six garden pupils to scholarships in accordance with a resolution adopted by the trustees at a meeting held in November 1889. Each scholarship conferred may be held by the recipient for a period not exceeding six years, subject to certain conditions. The holders of scholarships are repaid for their services to the Garden, and at the expiration of the six years are entitled to examination by the Garden Committee. On passing such examination to the satisfaction of the Committee and Director, they receive a certificate of proficiency in the theory and practice of gardening. The only scientific paper in the volume is, as we have just mentioned, a revision of the genus *Epilobium*, the American species occurring north of Mexico being those studied. This genus differs from all the other capsule-bearing *Onagraceæ*, except the Californian *Zauschneria*, in having its seeds provided with an ample coma at the apex. While it reaches great development in New Zealand, *Epilobium* is essentially a genus of temperate and cold climates, and the most widely distributed species are those of Arctic and Alpine regions. In Alaska a few such species occur, which are otherwise confined to the adjacent part of Asia. More widely distributed Arctic-Alpine immigrants from the Old World to the New are *E. spicatum*, *E. latifolium*, *E. palustre*, *E. alpinum*, &c. *E. hirsutum*, *E. parviflorum*, and *E. adnatum*, also occur as accidental waifs. The genus passes into South America along the backbone of the continent; few members of this family extend very far across the Mexican boundary in either direction. The most interesting biological features of the genus are those connected with the means of vegetative propagation, pollination, and dissemination. The contrivances by which species survive the winter, and are vegetatively propagated, in this respect attain an extreme degree of differentiation, one in particular having acquired aërial bulblets. The large-flowered species appear to be regularly proterandrous, the duration of the dichogamy being brief in most of them, and the smaller-flowered seem to be always synacmic and self-fertile, although with the probability of frequent intercrossing by aid of insects attracted by the nectar which is secreted within the calyx tube. The genus is of no striking economic value. The North American Epilobia have been mostly described by De Candolle, Torrey and Gray, Haussknecht and Barbey; the more notable works of more limited range being Hooker's "Flora Boreali-Americana," and Brewer, Watson, and Gray's "Botany of California." Prof. Trelease in his revision enumerates 38 species, which number includes the following novelties: *E. holosericeum*, *E. delicatulum*, and *E. clavatum*. The well-known sections *Chamænerion* and *Lysimachion* are still adhered to, the latter, of course, being by far the larger. In the analytical key the main divisions depend on whether the stigma is deeply 4-lobed or 4-cleft, or entire or only notched. Subdivisions are founded on whether the seeds are smooth, or papillately roughened. The name *E. spicatum*, Lam., is used instead of *angustifolium*, the typical *angustifolium* of Linnæus being, according to Prof. Haussknecht, what is commonly known as *E. Dodonæi*, Vill. We are glad to see that Prof. Trelease differs from Prof. Haussknecht in not adopting a new name for what is left of the original *E. alpinum* The *E. alpinum* of Linnæus included with this *E. Hornemanni* and *E. anagallidifolium*, but we think that the name may well stand for one of the segregates. The genus *Epilobium* has always proved a difficult subject; and Prof. Trelease is to be congratulated on his careful treatment, and successful arrangement, of the North American members. The 48 plates will be found of great help to students of these plants; they are not quite of uniform merit, but, taken as a whole, they give the essential details, stress being laid on the varied form of the stigma and seed. Additional illustrations are some well-reproduced photographs taken in the Garden, and a plan of the grounds (scale $\frac{1}{720}$) in five sections.

E. G. B.

OUR BOOK SHELF.

The Story of the Heavens. By Sir Robert Stawell Ball. Eighteenth Thousand. (London: Cassell and Company, 1891.)

In the preface to this edition, Sir Robert Ball remarks that he has taken the opportunity to "revise the work in accordance with the progress of astronomy during the last four years," and, generally speaking, new facts and theories are briefly referred to. A few points, however, are hardly brought up to date. For example, the spectrum of the Andromeda nebula is said to be "a faint continuous band of light" (p. 462), although it is now definitely known that this continuity does not exist. We also find no reference to the many stars now known to have bright lines in their spectra. The author thus misses a chance of exercising his well-known descriptive ability in an account of the connection between such stars and nebulæ; the similarity of the two being so considerable that Pickering has followed Lockyer in arranging them in a single group. Dr. Huggins's old view as to the coincidence of the nebula line with nitrogen is mentioned merely to be dismissed as erroneous. Why, therefore, is no notice taken of the suggested magnesium origin of the line—for, on any published evidence, the edge of the magnesium fluting is nearer the proper position than the nitrogen double? We would also point out that, according to recent observations, the apex of the sun's way is much nearer Lyra than Hercules. Telescopic changes in comets are fully described, but the accompanying changes in their spectra are not touched upon. Motions of stars in the line of sight are considered; but not those of nebulæ, although Mr. Keeler's observations have been published for some time. In fact, it may be said that there is a tendency to eschew spectroscopic questions, and hence much of the most beautiful part of the story of the heavens is left untold.

Notes on Elementary Physiography. By Horace C. Martin. (London and Manchester: John Heywood, 1891.)

The author has collected a lot of scraps of information from standard writers on physiographical matters, and has strung his gleanings together to form this book. And if he were an adept at compilation, and knew how to best arrange and connect facts, this plan of printing extracts *verbatim* might be commended. But when Mr. Martin selects notes which by themselves are incorrect, and interpolates in others crude statements which render them ridiculous, he does an injustice to the authors to whom he acknowledges his indebtedness, and he shirks responsibility by saying that "these notes do not lay claim to originality." Could anything be more misleading than the following description of sun-spots on p. 148? "They seem to rise suddenly to a great height, cool, and then sink back into the photosphere. They are due to uprushes of incandescent hydrogen, and are identical with the red flames seen during an eclipse." And the figure that accompanies this text cannot be a sun-spot at all, but must be something else inserted by mistake. Another blunder occurs on p. 59, where a section of an intermittent spring is shown upside down. The figures are mostly very coarse and poor, especially the moraines on p. 62, the section through a cinder cone on p. 89, and one of a volcano on p. 90; whilst the two figures of ocean bottoms on pp. 102 and 103 give a very wrong idea of their nature. There is, of course, a deal of information in the book, but no attempt is made to give it interest. In fact, although the author is a teacher of physiography, it is very evident from his work that he has not paid attention to the practical side of his science, or verified any of the phenomena he essays to describe. As a book of reference the work before us is untrustworthy; and as a work for students of elementary physiography it is useless and much to be condemned.

Thomas Sopwith, M.A., C.E., F.R.S.; with Excerpts from his Diary of Fifty-seven Years. By B. Ward Richardson, F.R.S. (London: Longmans, Green, and Co., 1891.)

MR. SOPWITH died in 1879 at the age of seventy-six. He was not eminent as an original scientific investigator, but he was a man of great vigour and freshness of mind, and had won the affection of a wide circle of friends by his genial and happy temper. For many years he resided at Newcastle as an engineer and railway surveyor. Afterwards he removed to Allenheads, where he served as the chief agent of Mr. T. W. Beaumont's lead-mines in Northumberland and Durham. Dr. Richardson's book will recall Mr. Sopwith vividly to the minds of his friends, and it contains many things which will be of interest even to readers who were not personally acquainted with him. During the long period of fifty-seven years he kept a diary regularly; and of this, of course, Dr. Richardson has made liberal use. The extracts show that Mr. Sopwith studied closely the currents of scientific opinion, and formed his own judgment about them in a shrewd and independent spirit.

Electric Transmission of Power.

YOUR article of the 1st inst. on the International Electrical Exhibition (p. 522), says: "In those days (before 1879) two wrong notions misled people—the one, that the maximum efficiency of a perfect electromotor could be only 50 per cent.; the other, quoting the remarks of Sir W. Siemens, 'in order to get the best effect out of a dynamo-electric machine, there should be an external resistance not exceeding the resistance of the wire in the machine.'"

These two notions are really one: the first follows by immediate inference from the second.

Your article says a little further on: "At the British Association in 1879, Prof. Ayrton exposed the fallacy of assuming that 50 per cent. was the maximum efficiency theoretically obtainable from an electromotor. . . . This was perhaps the first time that it had ever been suggested that the efficiency in electric transmission of power could be more than 50 per cent."

This is a mistake as to historical fact. Many years ago, I am not sure of the date, but it was long before the dynamo was invented, I had some conversation with the late Prof. Joule about mechanical equivalents and motive power, in which he told me that an electromotor (worked, of course, by a voltaic battery) had shown a very high percentage of efficiency—I think he said 79 per cent., and I am sure it was far above 50. I said, "How is that compatible with Ohm's demonstration that the efficiency of an electric circuit is at a maximum when the resistance of the battery is equal to that of the rest of the circuit?" to which he replied, "The maximum effect, in Ohm's theorem, does not mean the maximum work done by the oxidation of a given quantity of zinc, but the maximum effect obtainable from a given surface of zinc plates." "I see," said I, "just as in the case of the steam-engine, the problem of getting the maximum of useful effect from a given weight of coals is a different one from that of getting the maximum of power from a given area of piston."

This appears to be an instance of a truth being grasped by one of the great masters of science long before it passed into general teaching. And it is also an instance of a truth being so mistaken as to mislead: Ohm's law was evidently understood to bear a significance that it did not really bear.

Belfast, October 13. JOSEPH JOHN MURPHY.

[That Joule had clear and correct views regarding the efficiency of an electromotor driven by a voltaic battery was pointed out some years ago, being mentioned, for example, by Prof. S. P. Thompson in his book on "Dynamo-Electric Machinery." But in the paragraph quoted by Mr. Murphy from NATURE of October 1, the expression "electric transmission of power" had reference to the combination of apparatus exhibited at the lecture in question—had, in fact, the meaning usually attached to this expression, viz. the employment of a dynamo to convert mechanical energy into electric energy at one end of a pair of wires of some length, and the employment of a second dynamo at the other end of the wires to convert the electric energy back again into mechanical energy.

Now, not only would it have been somewhat difficult to foretell what would be the combined efficiency attainable by the employment of two dynamos as generator and motor, at a period "long before the dynamo was invented," but even down to 1879 no one had succeeded in practically transmitting power by means of this combination with an efficiency of as much as 50 per cent. over a distance of even one mile.

The only direct-current dynamo in common use at that date was the series-dynamo, and that machine, as is well known, differs radically in its behaviour from a voltaic battery. For while it is when a voltaic battery is developing a very small current that it gives power most economically to the outside circuit, the series-dynamo, when only a very small current is passing through it, develops practically no electromotive force, no power, and therefore has a very low efficiency. Hence, although electricians were undoubtedly mistaken in fancying that there was a theoretical limit of 50 per cent. in the efficiency when two dynamos were employed in the transmission of power, neither the error, nor its correction, were of that obvious character in 1879 that one might imagine from reading Mr. Murphy's letter.—W. E. A.]

Rain-making.

IN 1883 I published in NATURE (vol. xxviii., p. 83) an account of some experiments which I made to explain the curious phenomenon commonly seen at the Bocca of the Solfatara of Pozzuoli: paper or brushwood is kindled near the fumarole, and the action of the flame, even when its duration has been very brief, is observed for some time after in the relatively great increase of cloudy vapour that appears to roll out of the Bocca and to rise from the surrounding minor fumaroles. According to Prof. Arcangelo Scacchi, this increasd condensation of vapour is due to the carbon dioxide produced in the combustion; this gas causing condensation from the highly saturated medium in the same way as fumes become visible when concentrated hydrochloric acid is exposed to ordinary air. My experiments of 1883 tend to show that not only carbon dioxide, but (in accordance with the views of Dr. Aitken on the formation of cloud or mist) the increase of solid corpuscles made to float in the vapour-laden air inside or near the fumarole, might be the cause of a rapid and continuous condensing of the invisible vapour. I noticed that the "powdering" of the air with any kind of dust increased the cloudy column issuing from the Bocca of the Solfatara. I am therefore led to believe that the action of a paper- or faggot-flame in causing the increase of visible vapour from the Bocca of the Solfatara is due both to the production of carbon dioxide and to the increase of solid particles of soot and of light unburnt fragments made to rise and float in the air.

These experiments may help in explaining the action of explosives in causing a downfall of rain. Not only does the explosion produce a certain amount of carbon dioxide, but dust is widely scattered in the air, and carried upwards by the hot gases produced in the explosion. If the results of the experiments in Texas and Kansas by General Dyrenfurth and Prof. Curtis be confirmed, it would be interesting to see if the condensation of vapour in the atmosphere could be better insured by purposely increasing the quantity of dust produced in each explosion. The effect would perhaps be enhanced if the dust were of a markedly hygroscopical nature: the scattering in high air of very minute particles of calcium chloride should help in the making of cloud and rain. Weather Cycles and Severe Winters.

THE following view of the relations of severe winters is one which I do not remember to have seen stated.

Consider the 79 years 1812–90 (at Greenwich), and let us take, as a measure of winter cold, the mean temperature of the three months December, January, and February. Divide the series of years at 1860; giving a first series of 48 years (1812–59), and a second of 31 years (1860–90).

Now consider the first series. The coldest winter in it is 1813 (meaning, by that, 1813–14). The coldest of the following winters is 1829; the coldest of the following, 1840; then come (reckoning similarly) 1844 and 1846 (equal), 1854, 1859. The absolute order of decreasing severity is to some extent the same, but at certain points the order of time is reversed.

Next take the second series. The coldest winter in this is 1890 (*i.e.* 1890-91); the coldest of those preceding, 1878; the coldest of those preceding, 1870; then come (similarly) 1864 and 1860.

Thus we have a succession of severe winters of decreasing severity, and another, after it, of growing severity.

We may tabulate the data:—

Severe winters with lessening severity.	Mean temperature.	Severe winters with growing severity.	Mean temperature.
1813	31°·9	1860	37°·4
1829	33·2	1864	37·1
1840	33·9	1870	36·4
1844	34·9	1878	34·6
1846	34·9	1890	34·1
1854	35·6		
1859	37·4		

These data, put into the form of a graphic diagram, give a wave whose crest (mildest of the severe winters) we seem to have passed in the sixties. And it would appear judging by the past, that we have not yet reached the bottom of the hollow; but that after some years' interval we may have a winter even more severe than last, possibly we may have more than one, of growing severity.

It is right to state that, as far as 1856, the values of mean temperature used are those of Mr. Belleville, reduced to sea-level, as given in a paper by Mr. Eaton to the Royal Meteorological Society (Quarterly Journal, January 1888); after that date, those of Greenwich Observatory, published annually. The slight difference in kind does not materially affect the result.

In the *Meteorologische Zeitschrift* for September, M. Woeikof considers the question whether winters in Russia have been growing warmer, and his examination of the St. Petersburg records, from 1744 to 1890 (noting the number of cold days), leads to an affirmative answer. The number of very cold days has, on the whole, fallen off considerably in the later sixty-three years compared with the earlier, and in the second half of our century, as compared with the eighteenth and the earlier half of the nineteenth.

This, he finds, corresponds with popular opinion for Northern and Central Russia, according to which intense frosts have become more rare; but in the south, in the Crimea, the Caucasus, and Turkestan, there have been complaints of colder winters of late.

Mr. Glaisher some time ago expressed the view that our winters had been becoming milder. I have seen a criticism of this view, to the effect that the proximity of Greenwich to such a rapidly growing city as London might have to do with such a result. If the facts are as I have suggested above, a growing severity has taken the place of growing mildness, and the criticism referred to would fail to apply. A. B. M.

A Lunar Rainbow.

ON the evening of Saturday, October 17, at about 6.30 p.m., the rare and interesting phenomenon of a lunar rainbow was observed from Patterdale, Westmoreland. On the south-east, the moon, which had just risen, brightened the sky behind the mountains, while on the north-west there hung a uniformly dark and unbroken screen of haze or rain-cloud, which lightened off somewhat and was more scattered on the extreme west. With its highest point lying almost exactly north-west, a semicircle of pale whitish light was projected against this vapoury curtain. The bow was quite complete, but much brighter and sharper on its northern arc than on that falling south. The brighter portion fell over weird and clear into Glenridding (a favourite haunt of sun-painted rainbows), and as seen striped against the dark hill-sides of that valley, appeared to emit a pale-blue phosphorescent glare. At one time a shred of the dark smoky haze scudded over, but did not completely obscure the highest reaches of the spectral light. The radius appeared smaller than in the case of an ordinary solar rainbow, and the breadth of beam was about one-half thereof, or perhaps rather less. The spectacle having lasted for about eight minutes, light rain began to fall, and then the sky in a very short time became quite clear and star-lit, and all was over.

P. Q. KEEGAN.

Patterdale, Westmoreland, October 17.

The Destruction of Mosquitoes.

THE recent mention of this subject in your pages reminds me that I was told a few years ago by an English gentleman who has a most beautiful place on the Riviera that he had freed his property from this pest.

The property in question is a peninsula, and for that reason is exceptionally open to separate treatment. On the Riviera, as many of your readers will know, fresh water is a somewhat rare commodity, and all of it that the inhabitants can lay hold of is stored for future use in tanks or small receptacles.

The larva of the mosquito lives, as I understand, only in fresh water. Consequently, on the Riviera he is found in the tanks I have named.

The carp is, I am told, passionately fond of the larva of the mosquito, and the Englishman I refer to had extirpated the insect by putting a pair of the fish in every tank.

The plan is not one that could be adopted everywhere, but it is worth bringing under the notice of those whose circumstances are like those of the Riviera. S. A. M.

Law of Tensions.

POSSIBLY many science teachers find some little difficulty in satisfactorily demonstrating to a class the "law of tensions" for vibrating strings. In practice, unless the sonometer is fixed vertically, the error introduced by friction at the pulley (especially with heavy weights) is so great that the real tension is very different from that represented by the weight attached. Even if the apparatus be thus fixed, the changing of the weights occupies time, and a comparison wire is necessary, which must first be tuned to exact unison. The following admirable and very simple method was suggested to me by one of my students, and possibly there are some teachers to whom the idea is new.

Instead of applying tension by attaching weights, the result may be effected much more readily by means of an ordinary spring suspension-balance, such as is often used for weighing parcels. By this method the tension may be regulated to within half a pound, and increased or decreased so rapidly that the heightening of pitch is clearly recognized without the use of an auxiliary wire. H. G. WILLIAMS.

Congregational School, Caterham.

The Koh-i-Nur: a Reply.

IT is a far from pleasant task for me to set about replying to Prof. Maskelyne's criticism of my history of the Koh-i-Nur. I desire to say what must be said with all respect for him, but the tone of some of his remarks renders this a task of exceeding difficulty. All I care about is to get at the truth, and in order to do so I have spared neither time nor labour. I cannot suppose that you would grant me space sufficient for answering in detail all the statements in Prof. Maskelyne's article; nor do I seek for such space, because I deem it to be sufficient for those, several of them experts, who have accorded my views their hearty support and approval—Firstly, to state here in a general way that having very carefully studied Prof. Maskelyne's long article it has not, in my opinion, in the very smallest degree shaken the facts I have quoted, and the deductions from them which are to be found in my appendix to "Tavernier's Travels," and in the article published in the April number of the *English Illustrated Magazine* of the present year. Indeed, I might go further, and say that this attack very materially confirms the strength of the position upon which I have taken my stand. Secondly, I shall select a few points only which afford clear issues without any mystification, as to which side the balance of evidence lies upon, and invite readers to draw their own conclusions.

Before going further I think I should recall to notice the review of my edition of "Tavernier" which appeared in NATURE last February (vol. xliii. p. 313), and the *English Illustrated Magazine* for April, from which it will be seen that a suggestion made in the review has since been acted upon, with the result that was anticipated.

Prof. Maskelyne states that there is an absence of novelty in my facts. Just so, it is the old facts that I rely upon, not the misquoted and distorted variants which are to be found in so many writings. In my earliest allusions to this subject, many years ago, I made some mistakes, from blindly following authorities whom I now know to have been misled as to their facts. Since then I have learnt how necessary it is to check all statements as of fact in reference to this subject, and not to place too implicit a trust on quotations, no matter how eminent the authority who makes them may be.

Is it conformable to the judicial position which Prof. Maskelyne claims to occupy, to say that I dismiss Prof. H. H. Wilson, and what he narrates, "by the somewhat flippant remark that 'it has afforded sundry imaginative writers a subject for highly characteristic paragraphs'"? the facts being these—I never referred to Prof. H. H. Wilson; I did not even know before that he was the writer of the anonymous note in the official catalogue; and more than that, I had not that particular contribution to the subject in my mind when writing the above words.

Still further, with regard to the judicial position, I do not think it is apparent in any of Prof. Maskelyne's subsequent remarks. They are those of an advocate who smites his opponent in season and out of season, and seeks to disparage him by implying that he has assaulted the reputation of men (whom all must honour), when he has merely pointed out misquotations in their writings and expressed dissent with their conclusions.

I yield to no one in my admiration for the late Mr. King's work, but this cannot and should not restrain me from pointing out misquotations and misprints in his books when treating of the subjects with which he has dealt. To justify this I shall quote but a few instances which I have noticed, out of many. On pp. 78 and 82 ("Natural History of Precious Stones," Bohn's edition, 1870) the weight of the Mogul's diamond is stated as on Tavernier's authority to have been 240 carats and on the plate 208 carats, instead of 279$\frac{9}{16}$ carats.

The Koh-i-Nur is stated on p. 82 to have weighed 184 carats instead of 186$\frac{1}{16}$, and, strangest of all, when recut, that is to say in its present condition, its weight is given, pp. 75 and 347, as 102½ and on the plate as 102¼ carats, whereas its true weight is 105$\frac{1}{16}$ carats.

On p. 68 he deduces an argument from the note by Clusius, which is referred to by Prof. Maskelyne, and given in the original in my paper; the whole force of his argument depending, however, on the change of the word Belgium of the original to Europe in his, Mr. King's, own rendering of it.

I might add to this list, but sufficient has been stated to show that such statements require the most careful scrutiny, by whomsoever they may have been made.

On pp. 81–82 will be found Mr. King's dissent from Prof. Maskelyne's theory about the identity of Babar's diamond with the Mogul's; the difference of opinion between them being very wide indeed, though Prof. Maskelyne does not think it necessary to refer to it in his article.

With reference to what Prof. Maskelyne writes about De Boot and Garcia de Orta, I shall only say that I am very well acquainted with both authors' works, and that I assert again that the statement wrongly attributed to Monardes, and quoted as from Mr. King by Prof. Maskelyne, was an unsound and dangerous link in the chain by which it was proposed to connect Babar's diamond with the Koh-i-Nur.

It was a statement convenient to use, but what if I had used it first, and had also misquoted the authority? Would the terms Prof. Maskelyne employs about my aberration, &c., have been considered strong enough? There was, however, no aberration whatever on my part, and Prof. Maskelyne has himself now fully demolished, as anyone may read, the authenticity of the link he formerly used as a very material element in his chain. How can he, then, still cling to the fragments of this shattered link, while he dismisses so peremptorily Malcolm's statement about the weight of the Darya-i-Nur? Will he ever again use that link, or quote Monardes as his authority? (*Edinburgh Review*, vol. cxxiv., 1866, p. 247.)

I still venture to think that my conclusion as to the kind of carat used by Tavernier is a legitimate one. At the end of chapter xviii., book ii., he says, where computing from their weights the values of diamonds to a *liard*, "le Diamant du Grand Mogol pese 279$\frac{9}{16}$ carats" (*sic*); and in the very next paragraph, "le Diamant du Grand Duc de Toscane pese 139½ carats."

True it is, as pointed out by Prof. Maskelyne, that Tavernier in some other passages defines the carats as "nos carats"; he does not say, however, "carats de France," and the meaning therefore I take to be the carats employed by himself and his confraternity as contrasted with Indian measures of weight.

The value of the *abbas* or pearl *ratti* of 2·66 grains, or seven-eighths of the Florentine carat, has also been approximately arrived at by other relations given by Tavernier; conversely, therefore, it proves his carat to have been the Florentine.

I know of several early writers who have written about the Grand Duke's diamond, and by them Tavernier is referred to as *the* authority for its weight, which, as even Prof. Maskelyne admits, was given in Florentine carats. I think all the circumstances justify the belief that it was probably weighed by Tavernier himself with his own weights and scales. Now as to the weighment of the Mogul's diamond, in one passage Prof. Maskelyne (p. 557) states that Tavernier does not say he weighed any of the stones, and, in another, on the same page, "The diamond Tavernier saw, weighed, he said (was he merely told so or did he really weight it?), 319½ ratis."

The pages of Tavernier give the following very explicit answer to this query. He says, "Ce diamant appartient au Grand Mogol, lequel me fit l'honneur de me le faire montrer avec tous ses autres joyaux. On voit la forme où il est demeuré étant taillé, *et m'ayant esté permis de le peser jay trouvé qu'il pese 319½ ratis qui sont 279$\frac{9}{16}$ de nos carats.*"

This is precise evidence enough that he did weigh the stone himself, and if the carats were French instead of the lighter Florentine carats, which I believe them to have been, the stone was so much the heavier, and therefore still more removed in weight from Babar's stone.

Tavernier, I must remind the reader, besides Bernier, is our only authority for what is known about the Mogul's stone, as such, and what I have protested against and still protest against is, the suppression or rejection of such precise statements as the above, while others of his which fit in with particular theories are accepted.

In various directions I have been enabled to show Tavernier's minute accuracy about matters not connected with his trade as a jeweller, and when he speaks as an expert, in the practice of his own profession, he deserves, and proves that he deserves, a very different treatment from that which he has received. It is for this reason, and not because I am blind to his faults, that I give him my loyal support. I have already, in vol. ii. of "Tavernier's

Travels," stated that some corrections of values given in vol. i. are required in consequence of the identification, made too late for their correction, of the value of Tavernier's carat, but the present discussion as to the Koh-i-Nur is quite independent of that.

With regard to the mutilated condition of the Koh-i-Nur, I have nothing to add; the statement as to its condition, quoted by me, and the figures and models of the stone appear to be sufficient proof that portions had been removed by cleavage, which would account for the difference between its weight and the Mogul, as described by Tavernier, and I still retain that opinion.

It is not of the least importance as regards the main question, whether my suggestion should prove correct or not, that if Babar's stone has survived it may be identical with the Darya-i-Nur, to which Malcolm attributed a weight of 186 carats. Prof. Maskelyne, upon a system of calculation which I cannot admit as applicable to the case, as we do not know the thicknesses of the stones which he compares, gives to the Darya-i-Nur an estimated weight of 210 carats. For the present, therefore, I prefer Malcolm's definite statement to Prof. Maskelyne's theory about the attributed weight being the "echo associated with the Koh-i-Nur."

I shall have something to say about the Golconda table diamond, and about a great many other diamonds and other precious stones too, on a future occasion. In that work I shall be as careful to give, as I have hitherto been, chapter and verse for every statement of fact quoted, and I shall trust the histories so supported will find acceptance from those who care to investigate the evidence in favour of the conclusions connected therewith.

I am not quite sure that I appreciate the full force of the phrase "verisimilitude of a true history"—the last words of Prof. Maskelyne's article—but of this I am certain, that if ever I should see a history of the Koh-i-Nur following the lines of that article, I shall feel bound to make another and special "incursion" into the subject in defence of Tavernier if not of myself.

Dublin, October 12. V. Ball.

THE NAUTICAL ALMANAC.

It has been known for some little time that Dr. John Russell Hind, F.R.S., who for many years past has been responsible for the production of the national ephemeris, would soon seek that retirement to which his long services and his distinguished career entitle him. At the end of the year, he will relinquish the office of Superintendent of the "Nautical Alamanac," and the good wishes and kindly sympathy of the astronomers of many nations will follow him in the retirement he is seeking.

His successor has been appointed, and in Mr. A. M. W. Downing we have not the slightest doubt that the Admiralty have made a happy selection, and that under his auspices the high character and reputation of the "Nautical Almanac" will be fully maintained. Mr. Downing has long been associated with meridian astronomy in its best traditions; and in his position of greater responsibility and greater freedom we entertain the hope that his astronomical reputation will be fully maintained and extended. He may be said to enter on his office at a time when the "Nautical Almanac" is on its trial. The arrangement of the book, and the information it conveys, were practically settled by a Committee some sixty years since. How efficiently that Committee performed its task is shown by the fact that so little alteration has been needed for so long a period. But the outcry for change has gone forth: new committees are deliberating and reporting, and it will be among Mr. Downing's first duties to give shape, alike to the suggestions of irresponsible authorities, as well as to incorporate the recommendations of recognized committees in a new and improved "Nautical Almanac."

One great difficulty which has to be encountered, and of which it is not easy to see the proper solution, is due to the fact that the "Nautical Almanac" seeks to supply the wants of two very different classes of persons—namely, astronomers properly so called, and nautical men. The former demand very considerable detail in the exhibition of the several computations, the latter are satisfied with a very few final results. The former class is a small one, and a very moderate edition would satisfy their demands. The latter class is a very large one, and necessitates the printing, it may be, of thirty or forty thousand copies. The first question therefore, it seems, which must claim the attention of any Committee, or of any Superintendent, is, whether it be desirable to separate the "Nautical Almanac" into two, or it may be more, sections—one circulating among astronomers, the other among mariners. Private enterprise, anxious to minister to the wants of a rapidly increasing mercantile marine, has long supplemented the "Nautical Almanac" with a smaller and pirated edition, valuable to sailors, but detrimental to the circulation of what may be considered the legitimate ephemeris. Would it not be better if the Admiralty could see their way to publish an ephemeris with other nautical information, entirely for the use of the marine? Such a course is followed by the Governments of other countries. The German Government publish at Berlin a compact "Nautisches Jahrbuch," admirably adapted for naval purposes. This example is followed in Austria and in America, and we believe that the sale of our "Almanac" to the naval men of those countries has fallen off in the last years, or at least has not kept pace with the increase of foreign tonnage.

Such questions are of importance, as concerning not only the financial position of the work, but its influence in our own and foreign navies. There are, however, others touching the scientific and purely astronomical side of the compilation. Such, for instance, is the vexed question of the introduction of empirical terms in the final positions of the moon. Astronomical purists will maintain that the position of the moon should be that assigned by a purely gravitational theory, to facilitate the comparison of that theory with observation. Others demand that the place of the moon should coincide, as accurately as possible, with observation; and looking at the large portion of the "Nautical Almanac" devoted to "lunar distances," it would seem (if this section is ever used) that it is desirable that the distances given should represent observed facts. After a naval man has been at the trouble of observing and reducing a lunar distance, to ask him to apply a correction for the error of moon's place seems wanton and irritating. And if the amount of the empirical correction is clearly ascertainable, it can be easily removed before instituting a comparison between observation and that theory from which the moon's place has been computed. But to satisfy the demands of both classes of astronomers will try the tact and ability of the new Superintendent to the utmost.

The section devoted to the apparent places of the stars has also been submitted to considerable criticism. No doubt here enlargement is needed, and possibly improved places of the stars, particularly of circumpolar stars in the southern hemisphere, are much wanted. But on this point the new Superintendent is himself a weighty authority. He has worked much and successfully in the determination and removal of systematic differences from star catalogues, and their reduction to known and recognized standards. So that, under his influence, we may hope that this section will take and maintain a foremost position.

Mr. Downing has undertaken a very important duty, of great national importance, at a very critical period. We fully believe that he will grapple with this task successfully, and that, in his efforts to improve our ephemeris, he will have the assistance and support of all classes of astronomers.

RAIN-MAKING IN TEXAS.

IN NATURE of September 17 (p. 473), Mr. H. F. Blanford has discussed at considerable length the rain-making experiments in Texas, on the basis of such information as was attainable from newspaper reports. Inasmuch as these telegraphic reports have not only been inadequate, but also frequently inaccurate and misleading, the writer, who was the meteorologist of the Expedition, is led to give the following brief summary of the experiments and their results.

The experiments, which have been quite independent of the direction or patronage of the Weather Bureau, have been carried on by the Hon. R. G. Dyrenforth, Special Agent appointed by the Department of Agriculture. The plan of exploding oxy-hydrogen balloons was adopted as one of the principal methods to be employed, and several months were spent in preparing the necessary materials and apparatus. Preliminary experiments made in Washington demonstrated that a tremendous concussion could be produced by the explosion of balloons 10 feet in diameter, filled with a mixture of hydrogen and oxygen in the ratio of two to one. In addition to the explosion of balloons, preparations were made to fire sticks of dynamite carried up in the air by kites, and to explode rackarock (an explosive consisting of three parts of potassium chlorate to one part of nitrobenzol) and dynamite on the ground.

With materials for carrying out these three lines of experiment, the party went to an isolated ranch twenty-three miles north-west of Midland, Texas (lat. 32° 14′, long. 102° 12′). The inauguration of the experiments attracted great attention throughout the whole south-western section of the country, and, locally, people went from all the surrounding counties to witness the operations. Actual trial in the field soon developed the fact that the preparations for the balloon experiments were entirely inadequate. Accidents occurred to the furnaces for generating the gas, which took much time to repair, windy weather prevented the filling of the balloons, and a combination of other sources of delay rendered this line of experiment a practical failure. One or two balloons were exploded on several days, but these were too few in number and too infrequent to serve the purpose of an adequate experiment. Similarly it was found impossible with the small available force to operate the kites to advantage, and in windy weather they were quite unmanageable; so that, although, in all, quite a number of dynamite sticks were fired in the air in this way, yet as a line of effective experiment this also proved a failure. The only explosions that were made on a scale even approximately commensurate with the requirements were those of rackarock, and it may be stated that all the effective operations essential at Midland can be duplicated in every essential particular with 1500 pounds of rackarock together with 500 feet of wire and a small portable dynamo.

The first rain that occurred after the party reached Midland began shortly after noon on August 10, and continued at intervals until evening. The amount of rainfall was not measured, but it was stated in the language of the country to be a good "grass rain." The writer, who was *en route* to Midland, met similar sharp showers in the latter part of the afternoon near Sweetwater, 100 miles to the eastward. On the preceding evening some preliminary explosions had been made, but only on a small scale, and no result was anticipated. In the telegraphic despatch that was sent reporting the rainfall, no causative action was claimed—in fact, such action was explicitly disclaimed in the telegraphic report, which stated "we do not think the explosions actually produced the storm, as they were not on a large enough scale. The preliminary trial was made simply to test the efficiency of the special blasting powder." The firing, which was not over half-a-dozen blasts, was, then, simply a preliminary trial of material, and not in any sense an experiment to produce rain.

On August 16, 17, 18, and 20, cloudy weather very largely prevailed, and numerous thunderstorms were seen on the horizon that did not visit the ranch. On each of these days blasts of rackarock and of dynamite were fired while heavy cumulus or dense storm-clouds were in the field. In several instances, when a dense threatening cloud was overhead, a sharp detonating explosion of rackarock or of dynamite was followed at an interval of 30 to 40 seconds by a spatter of rain, or, if it was already sprinkling, the blast was followed by a very noticeable increase of the drops. This interesting result occurred a sufficient number of times to indicate that the phenomenon was a real effect of the explosions. On none of these days, however, was the amount of rainfall appreciable, except on the 18th, when it was two-hundredths (0·02) of an inch. The 18th opened cloudy, and old settlers predicted rain for the afternoon, whether the experiments should be made or not. To what extent, therefore, the explosions that were made were influential in producing the 0·02 inch that fell is obviously very difficult to determine, and as an evidence of the efficacy of the explosions it is practically valueless.

The next explosions were on the evening of August 21, when 156 pounds of rackarock were fired in 14 blasts. During the night a genuine norther came on, the wind blew from the north, the barograph curve rose rapidly, the temperature fell rapidly, and during the next forenoon a fine mist prevailed. This change of weather was quite extraordinary and unexpected, and with its accompanying mist was attributed to the heavy firing of the evening previous; but the norther had been on its way for several days, and the fine mist was evidently due to the uplifting by the cold north wind of the warm moist air of the plains. At numerous points in the State where the air was more humid a heavy rainfall occurred.

The last experiment, which in magnitude was the greatest of all, took place on the evening of August 25, after the writer had departed. The conditions were thought to be extremely unfavourable for rain, and the party was advised to wait for a more propitious occasion. The firing, however, was carried on until 11 p.m., when the party retired for the night. It is reported that "at 3 a.m. the heavy rolling of thunder disturbed the sleepers, heavy banks of clouds were seen advancing, almost constantly lighted by most brilliant lightning. An hour later the rain began to fall in torrents on the ranch, and did not cease till 8 a.m." Unfortunately, records of the *amount* of rainfall have not yet been received, but I am informed, by a gentleman who was present, that "it was nothing but a sprinkle." Further light is thrown on this rainfall by the weather map for 8 p.m. eastern time, of August 25. Rainfall is shown in New Mexico to the north-west of Midland, Texas, and the forecast officer made the following prediction: "For Eastern Texas, generally fair, except *local showers* on the extreme south-east coast *and the north-west*." Here we have an official prediction made in Washington City of probable showers over the district in which the experimenters were operating, and for the very night in which the thunderstorm followed the last of the explosions to produce rain.

In view of these facts, it is scarcely necessary for me to state that these experiments have not afforded any scientific standing to the theory that rain-storms can be produced by concussions. But, if the adherents of the theory maintain that "no experiment has been tried that is worthy of the name, and that no results ought to be looked for," it will be difficult to take opposite ground.

GEORGE E. CURTIS.

Smithsonian Institution, October 9.

COLOUR-BLINDNESS GENERALLY CONSIDERED.

COLOUR-BLINDNESS has now passed from the category of ailments denominated interesting, and is recognized as a visual infirmity the importance of which cannot be over-estimated. Before entering upon a discussion of the subject it will be well to lay down a definition of colour-blindness that shall run on all fours with the latest scientific findings in the matter. Colour-blindness is merely the inability of the eye to recognize the quality of the light that falls upon it, *i.e.* to discriminate between ether waves of varying refrangibility, the impingement of which upon the retina conveys to us the sensation of colour. Total colour-blindness is the inability to distinguish any colours. To a person so afflicted all bodies are either black, or white, or grey, according to the intensity of the light reflected from them. This form of the disease is very rare. Colour-blindness in ordinary is merely a question of degree, no two persons having exactly the same colour perception. A popular, but erroneous, belief respecting human vision is that good eyesight, *i.e.* accurate perception of form and distance, carries with it a keen perception of colours. This belief is deeply rooted, the impression that colour perception is an integral part of *good* eyesight being of almost universal adoption. The eye, however, that has the most perfect appreciation of form and distance *may* utterly fail to discriminate between two differently coloured objects of the same shape, and placed at equal distances from the observer. In this case a variation in the intensity of the light reflected from the objects under view would enable the colour-blind to discriminate between them, for along with colour ineptitude there generally exists the most delicate sense of discrimination as to the relative intensities of two sources of light.

The majority of people are undoubtedly afflicted with a mild form of colour-blindness. They are physically incompetent to differentiate exactly between the nicer shades of the more composite colours, such as browns, greys, and neutral tints. Yellow would appear to be the colour that gives least trouble to the colour-blind, and blue, if strongly illuminated, is readily recognized.

Red would appear to be the colour the want of the sense of which may be said to be characteristic of colour-blindness; and as a person blind to red is usually blind to its complementary colour, green, ordinary colour-blindness may thus be defined as the inability to discriminate between red and green. The normal eye would appear capable of analyzing white light into three coloured elements, one of which is red; the colour-blind eye, on the other hand, analyzes white light into two elements, neither of which is red. Why this visual defect should manifest itself in inability to distinguish that part of the spectrum which is the result of the slowest of the series of ethereal undulations is by no means clear. Physiological knowledge as to the exact relationship between external colour factors and our mental idea of colour is yet in its infancy. A consensus of opinion would, however, appear to obtain, that, of the rods and cones to which the nerve terminals of the retina are generally compared, the latter are responsible for the processes of analysis by which a compound ether wave is decomposed into its constituent elements, each of which produces an influence upon a corresponding nerve fibre. That the rods and not the cones are least responsible for our sensations of colour would appear to be borne out by the fact that among predatory animals, to whose nocturnal habitat a colour percipient apparatus would be an unnecessary adjunct, the cones are wanting, while the rods are very highly developed. Which theory may be ultimately accepted as best explaining the varied phenomena of colour-blindness is at present matter of speculation.

Authorities on colour-blindness are, however, agreed that in the majority of cases it is congenital; that to a great extent it is amenable to the same laws that govern the transmission of other hereditary tendencies; and while in some very few cases where it is induced by accident, such as concussion of the brain, or is the residual product of some malady or alcoholic excess, it may be palliated, yet colour-blindness is absolutely incurable.

The knowledge that something like 3 to 4 out of every 100 of our adult population are afflicted with colour-blindness is of serious importance, and statistics show that this is no over-estimation of the case. The following table shows the percentage obtained from a large number of cases:—

Examiner.	Number Examined.	Number Colour-blind.	Percentage.
Holmgren	32,165 men ...	1,019 ...	3·168
Dr. Joy Jeffries ...	18,556 ,, ...	764 ...	4·117
London Committee ..	14,846 ,, ...	617 ...	4·156
Total ...	65,567 men	2,400	3·66%

The percentage of female colour-blinds is much less. My own findings show 0·162; Dr. Joy Jeffries, however, found a lower proportion than this, as among 14,557 females tested only 11 were colour-blind.

This great disparity between the numbers of the colour-blind in the two sexes has been long known, and various causes have been assigned as accountable for it. As far back as 1855, Prof. Wilson, while admitting the superiority of colour perception in the female, could not believe that the number of colour-blind women were so few as compared with the number of men similarly afflicted. He took up the view that women were not so willing to be tested as men, so that unless they were members of some public institution it was quite a voluntary matter whether they were tested or not. He argued, too, that women attached greater importance to perception for colour than men do, and would consequently strive to screen their defect from others. Thus the only women who would voluntarily submit to be tested for colour would be those who had no doubt but they were possessed of perfect colour-vision.

Unfortunately, however, this method of reasoning is based upon an hypothesis altogether fallacious. Colour-blind people do *not* of themselves realize their condition. They cannot tell that there is any difference between red and green as they see them, and red and green as viewed by the normal eye.

The fact that females have more practice in handling colours than males is not sufficient to account for this disparity, unless we assume that the present condition of the female colour percipient is the resultant of the gradual development and training transmitted through ages of time. The superior colour percipience of the female must, we believe, be regarded as an inherent quality of the sex, which no amount of individual artificial training and practice can attain to.

There is just one thing, however, which may discount a little this feminine superiority. As colour-testing was first applied, too much importance was attached to the correct *naming* of colours, and as this is a province in which the masculine section of humanity is decidedly inferior, the ratio of male to female colour-blinds may have been increased in consequence. Assuming that the percentage of 3·66 of adult male colour-blinds is correct, we are confronted with the fact that there are over 4000 colour-blind seamen in the British mercantile marine. This number is exclusive of pilots, canal or lightermen, and firemen. Now, all of the 4000 are liable to be called upon to officiate as look-outs, *i.e.* they may be placed in circumstances where it is necessary they should distinguish instantaneously between the colours of the regulation side-lights of an approaching vessel. As far back as 1877, the Board of Trade, acting in accordance with the recommendation of the ophthalmic section of the British medical profession, came to the conclusion "that all candidates for masters' or mates' certificates shall pass a test examination as to their ability to distinguish the following colours, which enter largely into combination of signals by day or night used at sea; viz. black, white, red, green, yellow, and blue"; and they state that "the Board have been led to this decision because of the serious consequences which might arise from an officer of any vessel being unable to distinguish the colour of the lights and flags which are carried by vessels."

So far so good. But there the matter stopped. An officer failing to pass in colours is not deterred from going to sea; his certificate is simply endorsed "*failed to pass in colours*," and then it is optional with the owners, *if* they know of a man's colour imperfectness, to engage him or not. In the majority of cases they do not know. Wishing to obtain accurate information as to the views of the Liverpool shipowners upon this subject, I submitted to them the following queries:—

(1) Do you consider a colour-blind officer, mate, or captain, competent to have command of a vessel, steam or sailing?

(2) Would you consider a colour-blind man fit to be a look-out man?

In reply, 110 firms answered both questions in the negative, while *one* answered both in the affirmative.

Six said "Yes," to the first query, and "No," to the second.

Six expressed the opinion that no colour-blind officer should have command of a vessel; but that colour-blindness was not a barrier to a seaman officiating as look-out.

The language of the firms that answered both questions in the negative was such as to show that there was not the slightest hesitancy in the minds of the writers as to the utter undesirability, not to say danger, of employing a colour-blind man in any capacity in which he was responsible, in part or whole, for the safe navigation of the vessel.

Such expressions as "emphatically no," "absolutely unfit," "not fit to serve on a ship," "very unsuitable," &c., show in unmistakable terms the views held by Liverpool shipowners on the subject.

Liverpool shipowners certainly seem alive to the dangers of colour-blind *employés*. The practice of private examination would seem to be coming into common practice among first-class firms. But the Board of Trade have still to realize that look-out men, as well as officers, should not suffer from colour-blindness. If shipowners themselves deem it necessary for their own interests, and the safety of the *voyageurs* and property intrusted to their care, to debar colour-blind seamen from their service, it is surely incumbent upon the Board of Trade, in the interests of the travelling community over whose welfare they are supposed to preside, to make perfect colour-vision a *causa sine quâ non* that shall apply to *all* seamen of our mercantile marine. It is but fair, however, to that complex and overburdened instrument of government to add that they have introduced a so-called voluntary test, whereby a seaman, on payment of a fee of 1*s*., may be tested as to the perfectness of his vision for colour. Such a test must, from the very necessities of the case, be absolutely worthless. What A.B. would be likely, had he the slightest suspicion of his colour-blindness, to seek that confirmatory evidence which would debar him from following his calling? Sailors may be pardoned if they prefer to remain in a state of blissful ignorance as to their colour-vision, since they have nothing to gain, and possibly everything to lose, by undergoing an examination in colours. It must be admitted, however, that there are not wanting those who aver most positively that colour-blindness is not responsible for maritime disaster of any description whatever.

Rear-Admiral P. H. Colomb is of this opinion. In discussing the action of the Washington International Maritime Conference relative to colour-blindness, he stated, "I never knew myself a case of collision where colour-blindness was in question. The statements were generally perfectly clear that wrong helm was given deliberately in the face of the colour seen, and as no authoritative teaching had existed to show that it mattered what colour was seen as long as danger was denoted, I have never been able to lay stress on the colour-blind question."

Again, Admiral Colomb expressed the opinion "that collisions at night occurred through the helm being ported to the green light, and starboarded to the red light."

Undoubtedly this is a fertile source of disaster, but seamen, unless we assume them wilfully negligent, or astoundingly nervous, could hardly fail to act correctly at the critical moment in so many instances, if there were not some other factor at work which brought them to grief. I admit the truth of Admiral Colomb's statement as to collisions at night occurring through the helm being ported to the green light, and starboarded to the red. But I would go further, and inquire why such a wrongful procedure should be adopted in so many cases. I cannot believe it is done wilfully with the intent of causing collision, I cannot accept nervousness on the part of men, many of whom have spent a lifetime at sea, as the sole, or even a likely cause. I believe that in many cases the reason why the helm is ported to the green light and starboarded to the red light is that the persons responsible for the porting and starboarding are visually incapable of differentiating between one colour and the other.

Admiral Colomb's cause is undoubtedly the immediate means of effecting the collision; but that cause traced to its original source will, in the majority of cases, show neither negligence nor nervousness, but will stand revealed as the inevitable resultant of eyesight that cannot distinguish red from green. Pronouncements such as those quoted above, coming from those in high places, and pregnant with the weight of authority that usually attaches to such utterances, are mainly responsible for the general laxity and half-heartedness which are so characteristic of the Board of Trade's officials in respect to colour-blindness. A perusal of the records of inquiries into collisions at sea, or of the courts which settle questions of maritime and commercial law arising therefrom, reveals an astounding amount of conflictory evidence as to the relative positions of the colliding vessels as judged by their side-lights. It would be more charitable to suppose that the witnesses examined were colour-blind, rather than guilty of wilful and deliberate perjury. In such cases the question of a look-out's colour percipience is never discussed. An examination of the witness *on the spot*, as to his capability of discriminating between the port and starboard lights of a ship, would set at rest the question of his physical competence to assist in elucidating the problems under consideration.

The Dutch Government has long been alive to the dangers accruing from *induced* colour-blindness—I use the term induced in contradistinction to congenital—and adopt the most drastic measures to prevent a colour-blind officer from holding a position in their mercantile marine. Among other qualifications necessary to procure a warrant empowering a man to act as mate in the merchant marine, the royal order requires:—

"Colour perception perfect for transmitted light in one eye, and at least one half in the other, according to Donders's method."

Also that "the report and declaration of the expert, as required in the above, shall be considered valid for one month only from the time the test is made."

In Holland the tests are made by experts. In England they are applied by persons who, however well they may be qualified to examine candidates in navigation and seamanship, have certainly no *locus standi* in the matter of reporting upon the perfectness, or otherwise, of a man's visual organs.

The tests themselves that these navigation examiners have to apply are far from being perfect. They are established upon a wrong principle. Candidates are made to name colours, and according to the Parliamentary Report of 1887 "the only reasons for which they are reported as having failed are inability to distinguish red from green, and either from black by daylight, and red from green and either from ground glass by artificial light."

Candidates are first required to give correct colour names to a series of eight cards coloured black, red, green, pink, drab, blue, white, and yellow, respectively. A candidate is passed, however, if he names correctly the first three.

The second test consists in naming the colours of glasses some eleven in number, viz. ground glass, standard red, pink, three shades of green, yellow, neutral tint, two shades of blue, and white. The candidate need, however, only name the ground glass, the standard red, and the standard green.

Clearly, with such tests as these, the colour-blind may easily escape detection.

The Board of Trade return relative to colour tests for the year ending May 31, 1891, shows that out of 4688 candidates who presented themselves for masters' and mates' certificates, 31 were rejected on account of deficient colour sense. That these should be rejected after serving an apprenticeship to the sea, is manifestly unfair. The test should be applied at the commencement of their nautical career, and not when the initial stage is passed. Four of the 31 were reported as passing on subsequently undergoing examination, although medical expert opinion is emphatic in stating that colour-blindness is absolutely *incurable*. Perhaps it may be that the examiners were disposed, by their leniency in passing young men whose previous "failure in colours" proved them colour-blind, to atone in some slight form for the bad system which allows lads to spend the best years of their life in mastering the irksome details of a profession, before it informs them that they are visually unfitted for it. It is to be hoped that the investigation into the whole system of colour-testing at present being conducted by a committee appointed by the Royal Society, may lead to thorough and effective reforms.

T. H. Bickerton.

ON VAN DER WAALS'S TREATMENT OF LAPLACE'S PRESSURE IN THE VIRIAL EQUATION: A LETTER TO PROF. TAIT.

MY DEAR PROF. TAIT,—I gather from your letter of September 28 (Nature, October 8, p. 546) that you admit the correctness of Van der Waals's deduction from the virial equation (1) when the particles are infinitely small, in which case

$$\left(p+\frac{a}{v^2}\right) v = \tfrac{1}{2}\Sigma m V^2 \quad . \; . \; . \; . \; . \quad (1)$$

a representing a cohesive force, whose range is great in comparison with molecular distances; and (2) when, in the absence of a cohesive force, the volume of the particles is small in comparison with the total volume *v*, in which case the virial of the repulsive forces at impact gives

$$p(v-b) = \tfrac{1}{2}\Sigma m V^2 \quad . \; . \; . \; . \; . \; . \quad (2)$$

For hard spherical masses, the value of *b* is four times the total volume of the sphere. But you ask, "How can the factor $(v-b)/v$, which Van der Waals introduces on the left (in the first case) in consequence of the finite diameters of the particles, be justifiably applied to the term in K (or a/v^2) as well as to that in *p*?"

In my first letter I desired to avoid the complication entailed by the consideration of the finite size of the particles; but it appears to me that the argument there given (after Van der Waals) suffices to answer your question. For, if the cohesive force be of the character supposed, it exercises no influence upon any particle in the interior, and is *completely* accounted for by the addition to *p* of a/v^2. In so far, therefore, as (2) is correct when there is no cohesive force, the effect of such is properly represented by

$$\left(p+\frac{a}{v^2}\right)(v-b) = \tfrac{1}{2}\Sigma m V^2 \quad . \; . \; . \; . \quad (3)$$

in which *b* is to be multiplied by a/v^2, as well as by *p*.

Yours very truly,

October 13. Rayleigh.

NOTES.

At the Royal College of Physicians, on Monday, when the Harveian Oration was delivered by Dr. W. H. Dickinson, the Baly Medal was given to Prof. Michael Foster for distinction in physiology; the Morgan Medal to Sir Alfred Garrod for distinction in clinical medicine.

Dr. Dickinson, in the Harveian Oration, presented an admirably clear and vigorous account of Harvey's great discovery, and of the scientific results to which it has led. The earliest and most important of these results was the completion of Harvey's work by the discovery of the capillary system by Malpighi, who was born in the year in which Harvey published his famous treatise. "Harvey," said Dr. Dickinson, "had never seen a capillary, nor did the state of the microscope in his time allow of it. He was fain to conclude that the blood passed from the arteries to the veins partly by anastomoses but mainly by percolation, as water, to quote his own illustration, percolates the earth and produces springs and rivulets. Had it been possible, we may imagine the delight with which he would have witnessed the completion by vessels of his circular route." Dr. Dickinson also referred, among other results of Harvey's discovery, to embolism, and to our knowledge of inflammation, or at least as much of it as concerns the capillaries. In conclusion, he said:—"Knowledge has been advancing since Harvey's time in many and independent lines; the achievements of Bell, Bright, and Addison had no direct connection with his, but it is not too much to assert that the medicine of to-day is scarcely less permeated with the results of Harvey's discovery than is the human body with the circulation he discovered. It does not make him small to say that what he found out must have come to light had he never lived. If Columbus had not discovered America some one else must have done so before now. The law of gravity might even have been revealed in the fulness of time to another if not to Newton. But the discoverer is before his time; in this lies one measure of his praise; another, and a more important one, is in the results of his discovery."

The Electrical Exhibition, to be opened at the Crystal Palace on January 1 next, promises to be one of great interest and importance. The requests for space—which already exceed a total of 200—include electric lighting plants for country and town houses, for mines, for steamships, for railway trains, and even for private carriages. There are also included the newest forms of motors, generators, accumulators, and other machinery employed for producing and storing electricity. Several of the more important exhibits at the Frankfort Exhibition will be transferred to the Crystal Palace. The apparatus section will include a complete set of Sir William Thomson's standard electric instruments, new electro-medical and electro-thermic apparatus, the latest improvements in telephony and telegraphy, and also the most recent electrical appliances for war purposes, blasting, signalling, &c. Special buildings are now in course of erection for boilers and other heavy machinery.

The Municipality of Genoa has voted the sum of 15,000 lire in aid of the International Botanical Congress which is to be held in that city in September 1892 to celebrate the fourth centenary of the discovery of America.

The French Association for the Advancement of Science will meet at Besançon in 1893.

The Russian Geographical Society has awarded its great Constantine Medal to Prof. Sludsky for his researches into the figure of the earth and his geodetical work generally. Another Constantine Medal has been given to Prof. Pontebnya for his researches into the ethnography and the languages of the Great Russians, the Little Russians, and other Slavonians. His two works on the Russian grammar far surpass all previous works of the kind, not only in the number of examples but in the novelty and importance of his conclusions as to the structure of the Russian and other Slavonian languages; while his works on Great and Little Russian folk-lore are full of new and profound observations. The Count Lütke's medal has been awarded to S. D. Rylke for an elaborate work on the determinations of longitudes in Russia by means of the telegraph; the probable error of the chief determinations does not exceed 0·016 of a second of time. Another work of the same geodesist deals with the possible errors of levellings, as dependent upon temperature; they appear considerably to exceed those admitted in the best treatises on this subject. We also learn from Mr. Rylke's researches that the level of the Baltic Sea, as deduced from long series of observations, regularly sinks in the direction from north to south. Other gold medals have been awarded to Rovinsky, for a work on the geography and history of Montenegro; to M. Filipoff, for researches into the changes of the level of the Caspian Sea; to M. Obrutcheff, for a geological and orographical sketch of the Transcaspian region; and to M. Priklonsky, for a work on the Yakutes. Some silver medals have been awarded for works, chiefly in ethnography, of minor importance.

Dr. A. R. Forsyth, F.R.S., and Dr. M. J. M. Hill have been nominated to fill up the vacancies caused by the retirement of Dr. Hirst, F.R.S., and Mr. Lachlan from the Council of the London Mathematical Society.

Mr. Joseph Thomson has returned to England from South Africa, where he has been at work on behalf of the British South Africa Company. Accompanied by Mr. Grant, a son of Colonel Grant, he crossed the plateau between Lake Nyassa and Lake Bangweolo, and we learn from the *Times* that he has been able to make important rectifications in the geography of the Bangweolo region. The lake, as shown in our maps, is incorrectly laid down, mainly because the one definite and precise observation taken by Livingstone has not been adhered to. The lake is really only a backwater of the Chambeze (the source of the Congo), which enters from the east, and issues from the west of the lake as the Luapula. The lake, in fact, lies in a very slight depression of the plateau to the north of the Chambeze-Luapula. Even in the rainy season Mr. Thomson believes the lake does not exceed 20 feet at its deepest. The southern shores are clothed with forests, and, as a matter of fact, Mr. Thomson encamped far within the bed of the lake as it is laid down in most maps. In the rainy season the water of the lake spreads out, and covers for some distance the ground on which the forest stands.

Mr. W. L. Sclater, the Deputy Superintendent of the Indian Museum, Calcutta, will proceed to Upper Assam in December next, upon a collecting expedition for the benefit of the Museum. From Makum he will ascend the Dibing river in boats to the mouth of the Dapha, one of its confluents from the north, and establish his camp at some convenient spot in the Dapha valley. At the head of the Dapha valley rises Dapha Búm, a mountain of some 15 000 feet in altitude, on the frontiers of Chinese territory, so that there is a good prospect of the occurrence of Chinese forms in the district. The Dapha valley has been described geographically by Mr. S. E. Peal, who visited it in 1882 (see J.A.S.B., lii., pt. 2, p. 7), but has not been much explored zoologically. Mr. Sclater will pay special attention to mammals and birds.

Mr. Frank H. Bigelow, who has been acting as assistant in the U.S. Nautical Office, has been appointed to a newly-created professorship in the American Weather Bureau. His work will relate to terrestrial magnetism and solar physics, especially in their relation to meteorology.

News has been received of M. Paul Maury, who started in March last year for a botanical expedition in Mexico, and of whom nothing had been heard since his departure. He appears to have made a successful exploration of the province of Huasteca.

Dr. S. Winogradsky, of Zürich, has been appointed director of the scientific bacteriological section of the new Bacteriological Institute at St. Petersburg.

A notice which will be read with interest by owners of gems has been issued by Dr. A. Brezina, the Director of the Mineral Department of the Natural History Museum at Vienna. It relates to the doings of a young man who, on September 26, contrived to conceal himself in the Department just before the time for the closing of the Museum. He was caught, and found to be armed with a revolver, and to have in his possession files and other implements. He had also in his possession nearly 600 gems, some of them cut, but the majority in their natural state. He has a passport, in which he is described as Hugo Kahn, of Berlin; but he has also called himself Krony, Kronek, Kornak, Kronicsalsky. His age is twenty-four; he measures in height 170 cm.; he is slender, has a longish, handsome face, is of a brownish complexion, has dark hair, grey eyes, and a light-brown beard, which is of feeble growth. Upon the whole, he is an attractive-looking person. He has made several journeys in Germany, France, Switzerland, and Italy; and between the middle of July last and the beginning of September he travelled through Pyrmont, Ems, Strasburg, Basel, Milan, Genoa, Nice, Monaco, Genoa, Venice, to Vienna. Most of the gems (the names of which, with the exception of a rock crystal, he does not know) he professes to have bought from a barber in Marseilles. As it is important that the former owner or owners should be known, Dr. Brezina prints a list of the gems, with the request that anyone who has information about them will communicate with him.

On Monday the centenary of the Royal Veterinary College in Great College Street, Camden Town, was celebrated by a luncheon given in a tent which had been erected in front of the new buildings. The Duke of Cambridge, President of the College, took the chair, and the Prince of Wales was among the guests. In proposing the toast, "Success and continued prosperity to the institution," the Prince of Wales contrasted the important position of the College at the present day with its humble beginnings a hundred years ago.

We regret to record the death of the Rev. Percy W. Myles, of Bright's disease, at the comparatively early age of forty-two, at Ealing, on October 7. He was a man of great ability both in literary and scientific pursuits. He was a good botanist, and proved himself a most able editor of *Nature Notes*, the journal of the Selborne Society. The work with which his name will be identified is the "Pronouncing Dictionary of Botanical Names," appended to Nicholson's "Dictionary of Gardening"; it is now recognized as a standard work by botanists. Unfortunately his professional duties did not enable him to leave a margin; so that it is proposed to raise a "Myles Memorial Fund" on behalf of his widow; and any contributions will be thankfully received and at once acknowledged by the Rev. Prof. G. Henslow, Drayton House, Ealing, London, W.

THE Council of the Institution of Civil Engineers has issued a list of subjects on which it invites communications. The list is to be taken merely as suggestive, not in any sense as exhaustive. For approved papers, the Council has the power to award premiums, arising out of special funds bequeathed for the purpose. A detailed list is given of the awards made for original communications submitted during the past session.

MORE than ten earthquake shocks were felt in the island of Pantellaria, between Sicily and the Tunisian coast, between 5.30 p.m. and 4 a.m. on October 14–15. Some of the shocks were rather violent, and nearly all the inhabitants left their houses and passed the night in the streets or in the open country. According to intelligence received at the Central Meteorological Bureau, Rome, from Pantellaria on October 18, shocks of earthquake continued to be felt in the island. A remarkable phenomenon is announced in connection with these seismic disturbances. A new volcano has risen from the bed of the sea, not far from the coast of the island, and has been throwing up masses of stones and rubbish to a considerable height. A "slight eruption" from it was referred to in a telegram sent from Rome on October 20.

LAST winter there were some reports that sunset phenomena had greatly increased in brilliancy, as if something similar to the optical disturbance following the Krakatão eruption had occurred. Herr Busch has remarked (*Met. Zeit.*) how difficult it is to recognize gradual variations in such phenomena, or to say where they pass beyond the normal. Even the brown-red Bishop's ring may be regarded as quite normal in winter. A much more sure method of finding an optical disturbance of the atmosphere is measurement of the polarization of light. Herr Busch has carried this on systematically for some years with a Savart polariscope, and a simple instrument for measuring angles, determining the height of the two neutral points (Babinet's and Arago's) at sunset. Now, the values for this height, in February and May last, considerably exceed those obtained in the three previous years, and come near those in 1886, when the last traces of the great atmospheric disturbance were still everywhere perceptible. It would seem, then, that some optical disturbance has been really present, the beginning, extent, and cause of which, however, are in obscurity. The desirability of systematic observations in different places is pointed out.

IN our issue of October 8 (p. 549) we drew attention to three atlases issued by the Chief Signal Officer of the U.S. Army. We have now to record the publication, dated June 15 last, of an atlas containing seventy-two charts showing the normal temperature conditions in the United States and Canada by decades, three decades to each month, for 8h. a.m. and 8h. p.m., Washington time. Although the Signal Service has been in existence upwards of twenty years, it had not before been able to accumulate sufficient actual observations at any one hour, or set of hours, from which normal values could be derived. The values and isotherms contained in the present atlas are based upon nine years' observations, 1881–89. The charts have been carefully prepared, for the work of the Forecast Division, and will also be very useful in furnishing general information upon the average temperature of North America. The work has been prepared under the supervision of General Greely, although issued by the new Weather Bureau.

THE Ealing *Middlesex County Times* (October 17) prints the following account of an incident which occurred at "The Grange," the residence of Mr. Yates Neill, Ealing, on Wednesday, October 14:—"It appears that during Tuesday night a large branch of one of the magnificent chestnut trees standing in the ground was broken off by the force of the wind, and fell on two stripling chestnut trees near the wall. On Wednesday morning, the gardener, a man named Parker, was engaged in sawing the detached bough, Mr. Delancey Neill and Mr. Vertie Neill watching the operation. Just before noon, the first-named gentleman saw what appeared to him to be a ball of fire fall, and striking the tree in an oblique direction, alight on the ground within two or three yards of where the three were standing, whence it rebounded and exploded with a sound like dynamite. Although neither of them was struck, the shock was so great that for a time all three were dazed, Mr. Vertie Neill, indeed, being thrown down, and rolling over two or three times. His brother was the first to recover from the shock, and promptly went to his help, and he was removed to the house, where the feeling of dizziness speedily wore off; and beyond somewhat severe headaches, which lasted for some hours, neither of the gentlemen nor the gardener appeared to have suffered any ill effects. The trunk of the tree struck by the meteor presents the appearance of having been burned in a zigzag direction for a distance of some 20 or 30 feet."

MOST people who visit Greece devote their attention mainly to the remains of ancient art. Dr. Philippson, of Berlin, is of opinion that they might also with advantage spend some time in climbing the mountains of Greece. In the *Zeitschrift des Deutschen und Oesterreichischen Alpenvereins* he deals with the subject in a capital paper, which has been issued separately. He gives an attractive account of his own experiences in climbing Mount Chelmós, in the Peloponnese, describing admirably the impression produced upon him by the Styx. Dr. Philippson shows that in the Highlands of Greece there is still much good work to be done in topography, geology, and meteorology; and he sees no reason why some of it should not be accomplished by tourists.

MESSRS. W. H. ALLEN AND CO. have published a second edition of the late Mr. R. A. Proctor's "Other Suns than Ours."

THE new number of the *Internationales Archiv für Ethnographie* opens with a most interesting paper (in German) by Dr. J. Zemmrich on "The Islands of the Dead, and related Geographical Myths." The author shows how widely diffused is the belief that there are far-off happy islands, where all sorts of enjoyments are in store for the dead; and he suggests that Atlantis, about which so much has been written, was originally one of these mythical realms. Dr. J. Jacobs concludes his critical examination (in Dutch) of Dr. Ploss's view of the significance of circumcision.

MR. G. J. SYMONS, F.R.S., contributes to the current number of the Quarterly Journal of the Royal Meteorological Society a learned paper on the history of rain-gauges. It was read before the Society on March 18, in connection with the annual exhibition, and is one of the series in which hygrometers, anemometers, instruments for travellers, thermometers, sunshine recorders, barometers, marine instruments, apparatus for studying atmospheric electricity, solar radiation instruments, and the application of photography to meteorology, have been successively dealt with. Among the remaining contents of the number are papers on the following subjects: meteorological photography, by A. W. Clayden; on the variations of the rainfall at Cherra Poonjee, in the Khasi Hills, Assam (plate), by H. F. Blanford, F.R.S.; some remarkable features in the winter of 1890–91 (four illustrations), by F. J. Brodie; the rainfall of February 1891, by H. S. Wallis; "South-east Frosts," with special reference to the frost of 1890–91, by the Rev. F. W. Stow.

In the latest record of the proceedings of the Philosophical Society, Philadelphia, Dr. Daniel G. Brinton gives some vocabularies from the Musquito Coast. He obtained them from the Rev. W. Siebärger, a missionary of the United Brethren, now resident in that region. The most important of the vocabularies is a list of words from the language of the Ramas tribe, the only specimen of their tongue Dr. Brinton has ever secured. These people live on a small island in Blomfield lagoon. There are at present about 250 of them. All of them have been converted to Christianity, and, with the exception of a few very old persons, are able to speak and read English. Their native language is rapidly disappearing, and in a few years, probably, no one will use it fluently and correctly. They are large and strongly built, and are described as submissive and teachable. Their language has always been regarded as wholly different from that of the Musquito Indians, who occupy the adjacent mainland; and this is shown to be correct by the specimen sent to Dr. Brinton. It bears no relation, he says, to any other tongue along the Musquito Coast. It does not, however, stand alone, constituting an independent stock, but is clearly a branch, not very remote, of a family of languages once spoken near Chiriqui lagoon, and thence across—or nearly across—to the Pacific.

The Penang Administration Report for 1890 contains some interesting observations on the little-known aborigines of the Malay Peninsula. Observations made during the course of the year go to show that the Sakai (as distinguished from the Semang, or Pangan, as the Negrito tribes are called by the Malays of Perak and Pahang respectively) are far more numerous than was formerly supposed, and the President is of opinion that there may be more than 5000 men, women, and children in the district of Ulu Pahang alone. The country on both sides of the mountain range, which forms the watershed of the Jelai, Selom, Bidor, and Kampar rivers, is thickly inhabited by Sakai, who, although one or two large villages exist, live for the most part in groups of from two to three families. These Sakai are divided into two distinct tribes, called by themselves Sen-oi and Tem-be respectively, the former being the more civilized and more accessible tribe, while the latter are but little known to the Malays. Both the Tem-be and Sen-oi dialects, however, resemble one another so closely that it would seem to be evident that they originally sprang from the same source. Words to express any numerals higher than three are not found in the dialect of either tribe.

The mareograph in the harbour of Pola, according to Lieut. Gratzl (*Met. Zeitsch.*), often shows, in addition to the ordinary tidal curve, certain more or less regular oscillations, generally with a period of about 15 minutes (some with one of 7 minutes). These appear to be of the nature of *seiches*, and to be caused by squalls, which drive water from the open sea into the partly inclosed basin of the harbour, where it rises as a wave, retires, rises again to a less height (as only part of the surplus water escapes), and so on. Thus, in the evening of July 6, 1890, after a stiff west-north-west squall, there were eight pronounced oscillations, the strongest showing about 1·4 inch difference of level in 16 minutes. In another case, the harbour level rose higher than it had done for 15 years. The latter squall (a strong south-west one) affected also the Trieste mareograph, which showed nine wide oscillations with a mean period of 1 hour 46 minutes. Lieut. Gratzl suggests observations as to whether sudden impulses of "bora" against the Italian coast might not heap up the water there, so that a return wave might affect the Austrian mareographs; also whether certain sudden currents which injure fishermen's nets in the Dalmatian canals may not be connected with those waves.

A cat born with only two legs (the fore-legs being absent from the shoulder-blades) has been recently described by Prof. Leon of Jassy (*Naturw. Rundsch.*). It is healthy, and goes about easily, the body in normal position. When startled, or watching anything, it raises itself to the attitude of a kangaroo, using the tail as a support. This animal has twice borne kittens; in both cases two, one of which had four feet, the other only two.

We learn from Dr. Woeikof's notes of a journey in the Caucasus published in the Russian *Izvestia*, that the Russian Ministry of Ways and Communications has issued a very interesting work on the snow-slips of the Kazbek glaciers, accompanied by an atlas of maps and plans. Careful measurements of the variations in the position of the lowest end of the Devdorak glacier since 1878 have been made, and the results are given in the atlas. A house has been recently built close to the glacier, and it is connected by a road (available for horses) with the villages beneath. An experienced guide, who is bound to accompany the men of science and tourists who may intend to visit the glacier, stays in the house.

A kind of artificial honey which has lately been produced seems likely to become a formidable rival of natural honey. It is called "sugar honey," and consists of water, sugar, a small proportion of mineral salts, and a free acid; and the taste and smell resemble those of the genuine article. Herr T. Weigle brought the subject before a recent meeting of the Bavarian Association of the Representatives of Applied Chemistry, and there is a paragraph about it in the current number of the *Board of Trade Journal.*

Rats at Aden appear to have a vigorous appetite, and to adopt remarkable ways of gratifying it. Captain R. Light, writing on the subject from Aden to the Journal of the Bombay Natural History Society, says the rats in his house—which is overrun with them—demolish skins, braces, whips, &c.; and one night he awoke, feeling a rat gnawing at his toes. This happened in spite of a dog (a good ratter) being in the room. Captain Light was lately watching his pony being shod, and noticed the hoof apparently cut away all round the coronet, wherever it was soft. He accused the "nalband" of doing this in addition to the usual rasping of the hoof to suit the shoe. The "syce" said that the rats had done it, and that they came at night and ate away not only the pony's hoofs but those of the goat and kid, and that these animals were greatly tormented by the rats. Captain Light examined the hoofs, and found beyond doubt that such was the case, the marks of the teeth being plain; moreover, he found that the horns of the kid, which had been about half an inch high, were eaten flush with the head. Next morning, too, a large rat was discovered in the bedding under the horse. It had evidently been killed by a kick from him.

Two new methods of preparing azoimide, N_3H, the hydride of nitrogen isolated last year by Prof. Curtius, of Kiel, have been discovered. As announced at the time in NATURE (vol. xliii. p. 21), Prof. Curtius prepared this remarkable compound by reacting with his previously isolated hydrazine hydrate, $N_2H_4.H_2O$, upon hippuric acid, converting the hydrazine derivative thus obtained into its nitroso-derivative, and decomposing an alkaline solution of the latter with sulphuric acid. An aqueous solution of azoimide was obtained upon distilling the product of the latter operation. In order to obtain the free compound itself, the silver salt was prepared by allowing the distillate to flow into a solution of silver nitrate, and the precipitated silver salt, after drying, was decomposed with sulphuric acid. In a subsequent communication (comp. NATURE, vol. xliii. p. 378), Prof. Curtius, in conjunction with Dr. Radenhausen, showed that the pure compound was a very volatile liquid, boiling at 37°, and of fearfully explosive properties. In the current number of the *Berichte*, Drs. Noelting and Grandmougin, of Mülhausen, publish a preliminary note, in which they describe a new, and from the point of view of its constitution most important, method of preparing the liquid. The phenyl ester of azoimide is the diazobenzene imide of Griess,  $C_6H_5{-}N\left<\begin{array}{c}N\\ \|\\ N\end{array}\right.$, just as chlorbenzene is the phenyl ester of hydrochloric acid. In view of the great stability of the esters of aromatic radicles, it was hardly to be expected that diazobenzene imide would yield azoimide upon saponification. But Drs. Noelting and Grandmougin considered that it might be possible to obtain the latter by decomposing a nitro-derivative of diazobenzene imide by means of alkalies, inasmuch as the introduction of nitro-groups generally effects a considerable increase in the mobility of the acid radicle, rendering its removal by processes of saponification much less difficult. They therefore prepared the dinitro-derivative of diazobenzene imide from dinitro-aniline by means of the usual diazo-reaction—conversion into the perbromide, and treating with ammonia. When treated with alcoholic potash, this dinitro-diazobenzene imide readily decomposes into the potassium salt of dinitro-phenol and azoimide. Upon acidifying the product of the reaction and subjecting it to distillation, an aqueous solution of azoimide passes over, which may be converted into the anhydrous liquid by the method described by Prof. Curtius. The properties of the anhydrous azoimide obtained by this new method agree completely with those detailed by Prof. Curtius.

THE second new method of preparing azoimide was communicated by Dr. Thiele, of Halle, at the Versammlung deutscher Naturforscher und Aerzte, held in that city in September last. In the course of an investigation of the compounds of guanidine, nitro guanidine was obtained,  $C\left<\begin{array}{l}NH_2\\ =N{-}NO_2\\ NH_2\end{array}\right.$. Upon treating this compound with acetic acid and zinc dust, it is reduced to amido-guanidine, a substance which forms well-crystallized salts. By boiling the latter with soda, decomposition ensues, with formation of free hydrazine, N_2H_4, which may be very conveniently prepared by this method. Upon subjecting the nitrate to the diazo-reaction, the diazo-nitrate of guanidine is obtained,  $C\left<\begin{array}{l}NH_2\\ =N{-}N{=}N{-}NO_2\\ NH\end{array}\right.$. This compound readily breaks up on warming into two compounds, one of which is azoimide, and the other a complex acid of the composition CN_5H_3, and the curious constitution  $\begin{array}{lll}C & {=}N & {-}N\\ | & \;| & \;\|\\ NH_2 & NH & {-}N\end{array}$. The azoimide may be obtained by distillation in a manner similar to that described above.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. W. Harrow; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Cotton; a Common Marmoset (*Hapale jacchus*) from South-East Brazil, presented by Mrs. Trelawny; a Gannet (*Sula bassana*), British, presented by Mr. J. Hitchman; a Smooth Snake (*Coronella lævis*) from Hampshire, presented by Mr. F. C. Adams; ten Smooth Snakes (*Coronella lævis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

DISTRIBUTION OF LUNAR HEAT.—Mr. Frank H. Very's essay on the distribution of the moon's heat and its variation with the phase, which gained the prize of the Utrecht Society of Arts and Sciences in 1890, has recently been published. A bolometer in connection with a very sensitive galvanometer was used in the research, and the plan has been to project an image of the moon about 3 centimetres in diameter by a concave mirror; and to measure, not the heat from the whole of this, but only that in a limited part of it, from $\frac{1}{25}$ to $\frac{1}{30}$ of the area of the disk, the observations being repeated at different points and at different phases. Measures made six hours after full moon show that the east limb was hotter than the west limb in the proportion of 92·2 to 88·9. In one observation, made a day after full moon, the excess of heat at the east limb was much larger. There is a regular decrement of heat in passing from higher to lower latitudes, and observations on this point appear to indicate that heat is accumulated after many days of continuous sunshine. The heat in the circumferential zone of the full moon differs from that of the centre by about 20 per cent. In this respect, therefore, the thermal image is like the visual one. There seems to be some evidence that bright regions radiate a little more than dark during the middle of the lunar day; but this is not quite proved, and with a low altitude of the sun the effect is reversed. A comparison of the curve drawn by Zollner for the moon's light with that deduced from Mr. Very's observations brings out the point that visible rays form a much larger proportion of the total radiation at the full than at the partial phases, the maximum for light being much more pronounced than that for the heat. The diminution of the heat from the full to the third quarter is shown to be slower than its increase from the first quarter to the full. This result agrees with that obtained at Lord Rosse's Observatory, and is direct evidence of the storage of heat by lunar rocks.

GEOLOGICAL SOCIETY OF AMERICA.

THE Geological Society of America met at Washington on August 24 and 25. Owing to the death of the President, Prof. Alexander Winchell, Vice-President Gilbert took the chair.

The meeting was opened with an address on the late President by his brother, Prof. N. H. Winchell. Alexander Winchell was born on December 31, 1824, in Dutchess County, N.Y., and died at Ann Arbor on February 19 last. His work was many-sided. He had studied to be a civil engineer; had a strong leaning towards theology. He also read medicine and was a fine mathematician. He loved music, wrote poetry, and modelled in clay and plaster. As a financial resource he became a teacher, and was very successful. He became famous by his arguments on "The Bible History of the Creation," and published in the *Christian Advocate* "Adamites and Pre-Adamites," an exposition of Scriptural and scientific harmony. For four years he lectured on geology at Vanderbilt University. During his long connection with the University of Michigan he wrote many scientific articles of a popular nature, and did a great deal to popularize geological science. The speaker spoke eloquently of his dead brother's long and splendid connection with the Ann Arbor University. His death was most touchingly described. Oddly enough the last words he uttered in public were these: "When I speak to you again it will be of the inhabitants of another world." He had just finished his weekly lecture, and referred in his closing sentence to the subsequent lecture that was never delivered. He discovered many new geological species, and many other geologists testified their admiration for him by naming after him species they discovered. His great work for the Geological Society was touched on, and the speaker expressed his conviction that the next generation would keenly feel the beneficent influence of his brother's work. At the conclusion of the memorial Prof. Edward Orton, Dr. C. A. White, and Mr. C. R. Van Hise were appointed a committee to draft resolutions expressive of the Society's regret at the death of its President.

Prof. Dr. Gustav Steinmann, of the University of Freiburg, Germany, read the first paper, which consisted of the description of a geological map of South America. A large copy of the map was hung up beside the platform, and small replicas were distributed among the audience. Dr. Steinmann, who is a young, bearded, spectacled, typical German student, was sent to

South America by the Strasburg University some ten years ago, and spent some two years making a most thorough research in the geology of the continent, the tangible result being the remarkably complete map exhibited. His researches in South America prove that there is a most remarkable similarity between the geology of the two Americas, and especially between the geology of the southern United States and the southern continent.

The second paper was by Dr. August Rothpletz, of the University of Munich, Germany, on the Permian, Triassic, and Jurassic formations in the East Indian Archipelago. The doctor's paper was devoted to the description of some Mesozoic and Palæozoic fossils collected in two of the Indian islands by his friend Dr. Wichmann, during a geological exploration of the islands. Dr. Wichmann being geologist of the University of Utrecht, Holland, the collections were of particular value, and Dr. Rothpletz's description and classification of them, to which he devoted his paper, was thorough and minute. He took occasion to ridicule some of the classifications of fossils which put them in one category when found in one place and in another when found somewhere else.

"Thermometamorphism in Igneous Rocks" was the title of the next paper presented. It was by Mr. Alfred Harker, of St. John's College, Cambridge, England, and dealt with the effects of high volcanic temperatures in the formation of rocks. He described the results of his researches in the lake region of England, where the volcanic forces of nature were particularly well marked.

Prof. Alexis Pavlow of the University of Moscow, Russia, presented a paper entitled "Sur les Couches Marines terminant le Jurassique et commençant le Crétace, et sur l'Histoire de leur Faune."

Another paper, also in French, presented by Prof. Max Lohest, of the University of Liége, Belgium, was entitled "Sur l'Homme contemporain du Mammouth en Belgique." The contemporaneous existence of man was supported by proofs additional to those heretofore given.

Baron Gerald de Geer, of Sweden, gave an interesting account of recent changes of level along the sea-board of the Scandinavian peninsula.

The most important new matter presented was a paper on "Fossil Fishes of the Lower Silurian Rocks of Colorado," by Mr. C. D. Walcott, of the United States Geological Survey. The discovery of the fossil fish remains is of recent date, and attracts great attention among zoologists and geologists from its carrying back into the past, over a great time interval, our knowledge of vertebrate life. They are the oldest vertebrate remains known, and appear to be the ancestral types of the great ichthyic fauna of the classic "old red sandstone" of Europe, and the Devonian group of America.

In the discussion, Profs. Von Zittel, Jaekel, and F. Schmidt compared the fish remains exhibited with those of the Devonian, and stated that the Upper Silurian types were not represented in the fauna.

SECOND DAY.—From the committee appointed to draft appropriate resolutions relative to the death of Dr. Alexander Winchell, the President of the Society, Prof. Orton made a report which was adopted. The resolutions reported paid a just and touching tribute to the character of the deceased, and fittingly acknowledged the great services which he had rendered to the science in the course of the forty years of arduous and unremitting toil which he had devoted to its investigation. To his writings and lectures were attributed in a great degree the growing liberality and enlargement of thought of the more serious-minded portion of the community in regard to the theory of organic evolution as presented by Darwin and his successors. Dr. Winchell, the report affirmed, stated and defended with marked ability and courage and persuasive power this the most characteristic and far-reaching doctrine of modern geological science. "The first enunciation of this doctrine," the report stated, "was sure to awaken distrust and even bitter hostility among a large class of people because of its apparent incompatibility with some of their most fundamental convictions and beliefs. To disregard the sincere apprehension of this great class, comprising, as it does, so much of the moral and intellectual force of the body politic, would be heartless. To mock at its fears, ill founded though they were, would be worse. What worthier service to science and the community than to disarm hostility by showing that the evolutionary philosophy, so far from degrading and dishonouring man, makes him in a peculiar sense the head and crown of the creation?"

In seconding the resolutions Dr. C. A. White paid a warm tribute to Dr. Winchell, with whom he had been on terms of intimacy for many years. As a further mark of respect the resolutions were adopted by a rising vote.

The first paper presented was by Dr. Frederick Schmidt, of St. Petersburg, Russia.

Prof. Gregoire Stefanescu, of the University of Bucharest, Roumania, presented "Sur l'Existence du Dinotherium en Roumanie," the next paper. The Professor read it in French, illustrating it by drawings on the blackboard, and after he had finished, Prof. Dr. Charles Barrois read it over again in English, so that those who did not know French might not lose it. Though quite short the paper was very interesting. It briefly described a large number of bones of the Dinotherium found widely distributed over Roumania, which indisputably pointed to the existence of this almost unknown extinct animal in that land countless years ago. This was probably the largest mammal that ever inhabited the earth, its epoch being the Tertiary period. It had enormous tusks, that curved downward and backward in such a way that it could only hurt itself with them, and probably had a massive trunk. In character it more nearly resembled the elephant and rhinoceros of modern ages than any other known animal.

Prof. A. N. Krassnof, of the Charkow University, Russia, read the next paper on the black earth of the steppes of Southern Russia, its origin, distribution, and points of resemblance with the soils of the prairies of America. The paper traced the resemblance between the Russian steppes and the American prairies to their similar origin in the layers of the vegetables of years. Their remarkable fertility was touched on generally, and a technical account of the origin of the two plains was given.

TECHNICAL CHEMISTRY.

IN his Cantor Lectures on Photographic Chemistry, delivered last spring before the Society of Arts, and just issued by the Society in a separate form, Prof. Meldola opens with some remarks on the special position of technical training in chemistry, which should be carefully conisdered in connection with the present widespread movement in the direction of technical education throughout the country. He says:—

"There are many who identify technical instruction with the teaching of some handicraft, a notion which has no doubt arisen from the identification of technical skill with manual dexterity in some mechanical industry. By the adoption, either tacitly or openly, of this narrow definition, the chemical industries have suffered to a very large extent in this country, because their progress is more dependent on a knowledge of scientific principles, and much less dependent on manual dexterity than any of the other subjects dealt with in schemes of technical instruction. Now, in order to give technical instruction in a subject like photography, which is so intimately connected with chemistry, we may adopt one of two courses. The student may become a practical photographer in the first place, and may then be led on to the science of his practice by an appeal to the purely chemical principles brought into operation. This may be called the analytical method. The other method is to give the student a training in general chemistry first, and then to specialize his knowledge in the direction of photography. This may be regarded as a synthetical method.

"In other departments of technology, and especially in those where the underlying principles are of a mechanical nature, the analytical method may be, and has been, adopted with success. It is possible to lead an intelligent mechanic from his every-day occupations to a knowledge of the higher principles of mechanical science by making use of his experience of phenomena which are constantly coming under his notice. From this it is sometimes argued by those who are in the habit of regarding technical instruction from its purely analytical side, that technical chemistry can be taught by the same method. Some teachers may possibly succeed in this process, but my own experience, both as a technologist and a teacher, has led me to the conclusion that, for chemical subjects, the analytical method is both too cumbersome and circuitous to be of any real practical use. No person engaged in chemical industry in any capacity—whether workman, foreman, manager, or proprietor—can be taught the principles of chemical science out of his own industry, unless he has some considerable knowledge of general principles to start with. No person who is not grounded in such broad principles can properly appreciate the explanation of the phenomena with which his daily experience brings him into contact, and if his previous training is insufficient to enable him to understand the nature of the changes which occur in the course of his operations, he cannot derive any advantage from technical instruction. These remarks will, I hope, serve to emphasize a distinction which exists between technical chemistry and other technical subjects, and I have thought it desirable to avail myself of the present opportunity of calling particular attention to this point, because it is one which is generally ignored in all discussions on technical education.

"The reason for this difference in the mode of treatment of chemical subjects is not difficult to find. The chemical technologist—the man who is engaged in the manufacture of useful products out of certain raw materials—is, so far as the purely scientific principles are concerned, already at a very advanced stage, although he may not realize this to be the case. The chemistry of manufacturing operations, even when these are of an apparently simple kind, is of a very high order of complexity. There are many branches of chemical industry in which the nature of the chemical changes undergone by the materials is very imperfectly understood; there is no branch of chemical industry of which the pure science can be said to be thoroughly known. For these reasons I believe that I am justified in stating that the chemical technologist is working at a high level, so far as the science of his subject is concerned, and this explains why he cannot be dealt with by the analytical method.

"The general considerations which have been offered apply to the special subject of photography with full force. A person may become an adept as an operator without knowing anything of physics or chemistry; there are thousands of photographers all over the country who can manipulate a camera and develop and print pictures with admirable dexterity, who are in this position. If we adopt the narrow definition of technical instruction, we should appoint such experts in our Colleges, and through them impart the art of taking pictures to thousands of others. But would our position as a photographing nation be improved by this process? I venture to think not. We might be carrying out the ideas of certain technical educators by adopting this method, but I do not imagine that in the long run the subject itself would be much advanced; our position in the scale of industry would not be materially raised by the wholesale manufacture of skilful operators. And so with all other branches of applied chemistry; it is technologists whose knowledge is based on a broad foundation that are wanted for the improvement of our industries. These are the men who are raised in the technical high schools of the Continent, and whose training the Continental industries have had the wisdom to avail themselves of."

AN ASTRONOMER'S WORK IN A MODERN OBSERVATORY.[1]

THE work of astronomical observatories has been divided into two classes, viz. astrometry and astrophysics. The first of these relates to astronomy of precision, that is to the determination of the positions of celestial objects; the second relates to the study of their physical features and chemical constitution.

Some years ago the aims and objects of these two classes of observatories might have been considered perfectly distinct, and, in fact, were so considered. But I hope to show that in more recent years their objects and their processes have become so interlaced that they cannot with advantage be divided, and a fully equipped modern observatory must be understood to include the work both of *astrometry* and *astrophysics*.

In any such observatory the principal and the fundamental instrument is the transit circle. It is upon the position in the heavens of celestial objects, as determined with this instrument or with kindred instruments, that the whole fair superstructure of exact astronomy rests; that is to say, all that we find of information and prediction in our nautical almanacs, all that we know of the past and can predict of the future motions of the celestial bodies.

Here is a very small and imperfect model, but it will serve to render intelligible the photograph of the actual instrument which will be subsequently projected on the screen. [Here the lecturer described the adjustments and mode of using a transit circle.]

We are now in a position to understand photographs of the instrument itself. But first of all as to the house in which it dwells. Here, now on the screen, is the outside of the main building of the Royal Observatory, Cape of Good Hope. I select it simply because, being the observatory which it is my privilege to direct, it is the one of which I can most easily procure a series of photographs. It was built during the years 1824–28, and like all the observatories built about that time, and like too many built since, it is a very fair type of most of the things which an observatory should not be. It is, as you see, an admirably solid and substantial structure, innocent of any architectural charm, and so far as it affords an excellent dwelling-place, good library accommodation, and good rooms for computers, no fault can be found with it. But these very qualities render it undesirable as an observatory. An essential matter for a perfect observatory should be the posssibility to equalize the internal and the external temperature. The site of an instrument should also be free from the immediate surroundings of chimneys or other origin of ascending currents of heated air. Both these conditions are incompatible with thick walls of masonry and the chimneys of attached dwelling houses, and therefore, as far as possible, I have removed the instruments to small detached houses of their own. But the transit circle still remains in the main building, for, as will be evident to you, it is no easy matter to transport such an instrument.

The two first photographs show the instrument, in one case pointed nearly horizontally to the north, the other pointed nearly vertical. Neither can show all parts of the instrument, but you can see the massive stone piers, weighing many tons each, which, resting on the solid blocks 10 feet below, support the pivots. Here are the counter-weights which remove a great part of the weight of the instrument from the pivots, leaving only a residual pressure sufficient to enable the pivots to preserve the motion of the instrument in its proper plane. Here are the microscopes by which the circle is read. Here the opening through which the instrument views the meridian sky. The observer's chair is shown in this diagram. His work appears to be very simple, and so it is, but it requires special natural gifts, patience and devotion, and a high sense of the importance of his work to make a first-rate meridian observer. Nothing apparently more monotonous can be well imagined if a man is "not to the manner born."

Having directed his instrument by means of the setting circle to the required altitude, he clamps it there and waits for the star which he is about to observe to enter the field. This is what he sees. [Artificial transit of a star by lantern.]

As the star enters the field it passes wire after wire, and as it passes each wire he presses the key of his chronograph and records the instant automatically. As the star passes the middle wire he bisects it with the horizontal web, and again similarly records on his chronograph the transit of the star over the remaining webs. Then he reads off the microscopes by which the circle is read, and also the barometer and thermometer, in order afterwards to be able to calculate accurately the effect of atmospheric refraction on the observed altitude of the star; and then his observation is finished. Thus the work of the meridian observer goes on, star after star, hour after hour, and night after night; and, as you see, it differs very widely from the popular notion of an astronomer's occupation. It presents no dreamy contemplation, no watching for new stars, no unexpected or startling phenomena. On the contrary, there is beside him the carefully prepared observing-list for the night, the previously calculated circle setting for each star, allowing just sufficient time for the new setting for the real star after the readings of the circle for the previous observation.

After four or five hours of this work, the observers have had enough of it; they have, perhaps, observed fifty or sixty stars, they determine certain instrumental errors, and betake themselves to bed, tired, but (if they are of the right stuff) happy and contented men. At the Cape we employ two observers—one to read the circle, and one to record the transit. Four observers are employed, and they are thus on duty each alternate night. Such is the work that an outsider would see were he to enter a working meridian observatory at night, but he would find out, if he came next morning, that the work was by no means over. By far the largest part has yet to follow. An observation that requires only two or three minutes to make at night, requires at least half an hour for its reduction by day. Each observation is affected by a number of errors, and these have to be determined and allowed for. Although solidly founded on massive piers resting on the solid rock, the constancy of the instrument's position cannot be relied upon. It goes through small periodic changes in level, in collimation, and in azimuth, which have to be determined by proper means, and the corresponding corrections have to be computed and applied; and, also, there are other corrections for refraction, &c., which involve computation and have to be applied. But these matters would fall more properly under the head of a special lecture upon the transit instrument. I mention them now, merely to explain why so great a part of an astronomer's work comes in the daytime, and to dispel the notion that his work belongs only to the night.

---

[1] Friday Evening Discourse delivered at the Royal Institution by Dr. David Gill, F.R.S., Her Majesty's Astronomer at the Cape of Good Hope, on May 29, 1891.

One might very well occupy a special lecture in an account of the peculiarities of what is called personal equation—that is to say, the different time which elapses for different observers between the time when the observer believes the star to be upon the wire, and the time when the finger responds to the message which the eye has conveyed to the brain. Some observers always press the key too soon; some always too late. Some years ago I discovered, from observations to which I will subsequently refer, that *all* observers press the chronograph key either too soon for bright stars or too late for faint ones.

Other errors may, and I am sure do, arise both at Greenwich and the Cape, from the impossibility of securing uniformity of outside and inside temperature in a building of strong masonry. The ideal observatory should be solid as possible as to its foundations, but light as possible as to its roof and walls—say, a light framework of iron covered with canvas. But it would be undesirable to cover a valuable and permanent instrument in this way.

But here is a form of observatory which realizes all that is required, and which is eminently suited for permanent use. The walls are of sheet iron, which readily acquire the temperature of the outer air. The iron walls are protected from direct sunshine by wooden louvres, and small doors in the iron walls admit a free circulation of air. The revolving roof is a light framework of iron covered with well-painted *papier-maché*.

The photograph now on the screen shows the interior of the observatory, and this brings me to the description of observations of an entirely different class. In this observatory the roof turns round on wheels, so that any part of the sky can be viewed from the telescope. This is so, because the instrument in this observatory is intended for purposes which are entirely different from those of a transit circle. The transit circle, as we have seen, is used to determine the *absolute* positions of the heavenly bodies; the heliometer, to determine with greater precision than is possible by the absolute method the *relative* positions of celestial objects.

To explain my meaning as to absolute and relative positions. It would, for example, be a matter of very little importance if the absolute latitude of a point on the Royal Exchange or the Bank of England were one-tenth of a second of arc (or 10 feet) wrong in the maps of the Ordnance Survey of England—that would constitute a small *absolute* error common to all the buildings on the same map of a part of the city, and common to all the adjoining maps also. Such an error, regarded as an *absolute* error, would evidently be of no importance if every point on the map had the same absolute error. There is no one who can say at the present moment whether the absolute latitude of the Royal Exchange—nay, even of the Royal Observatory, Greenwich—is known to 10 feet. But it would be a very serious thing indeed if the relative positions on the same map were 10 feet wrong *here* and *there*. For example, if of two points marking a frontage boundary on Cornhill, one were correct, the other 10 feet in error, what a nice fuss there would be! what food for lawyers! what a bad time for the Ordnance Survey Office! Well, it is just the same in astronomy.

We do not know, we probably never shall know with certainty, the absolute places of even the principal stars to one-tenth of a second of arc. But one-tenth of a second of arc in the measure of some relative position would be fatal. For example, in the measurement of the sun's parallax an error of one-tenth of a second of arc means an error of 1,000,000 miles, in round numbers, in the sun's distance; and it is only when we can be quite certain of our measures of much smaller quantities than one-tenth of a second of arc, that we are in a position to begin seriously the determination of such a problem as that of the distances of the fixed stars. For these problems we must use differential measures—that is, measures of the relative positions of two objects. The most perfect instrument for such purposes is the heliometer.

Lord McLaren has kindly sent from Edinburgh, for the purposes of this lecture, the parts of his heliometer which are necessary to illustrate the principles of the instrument.

This instrument is the same which I used on Lord Crawford's expedition to Mauritius in 1874. It was also kindly lent to me by Lord Crawford for an expedition to the Island of Ascension to observe the opposition of Mars in 1877. In 1879, when I went to the Cape, I acquired the instrument from Lord Crawford, and carried out certain researches with it on the distances of the fixed stars.

In 1887, when the Admiralty provided the new heliometer for the Cape Observatory, this instrument again changed hands. It became the property of Lord McLaren. I felt rather disloyal in parting with so old a friend. We had spent so many happy hours together, we had shared a good many anxieties together, *and we knew each other's weaknesses so well*. But my old friend has fallen into good hands, and has found another sphere of work.

The principle of the instrument is as follows. [The instrument was here explained.]

There is now on the screen a picture of the new heliometer of the Cape Observatory, which was mounted in 1887, and has been in constant use ever since. It is an instrument of the most refined modern construction, and is probably the finest apparatus for refined measurement of celestial angles in the world.

[Here were explained the various parts of the instrument in relation to the model, and the actual processes of observation were illustrated by the images of artificial stars projected on a screen.]

Here, again, there is little that conforms to the popular idea of an astronomer's work; there is no searching for objects, no contemplative watching, nothing sensational of any kind. On the contrary, every detail of his work has been previously arranged and calculated beforehand, and the prospect that lies before him in his night's work is simply more or less of a struggle with the difficulties which are created by the agitation of the star images, caused by irregularities in the atmospheric refraction. It is not upon one night in a hundred that the images of stars are perfectly tranquil. You have the same effect in an exaggerated way when looking across a bog on a hot day. Thus, generally, as the images are approached, they appear to cross and recross each other, and the observer must either seize a moment of comparative tranquillity to make his definitive bisection, or he may arrive at it by gradual approximations till he finds that the vibrating images of the two stars seem to pass each other as often to one side as to the other. So soon as such a bisection has been made, the time is recorded on the chronograph, then the scales are pointed on and printed off, and so the work goes on, varied only by reversals of the segments and of the position circle. Generally, I now arrange for thirty-two such bisections, and these occupy about an hour and a half. By that time one has had about enough of it, the nerves are somewhat tired, so are the muscles of the back of the neck; and if the observer is wise, and wishes to do his best work, he goes to bed early and gets up again at two or three o'clock in the morning, and goes through a similar piece of work. In fact, this must be his regular routine night after night, whenever the weather is clear, if he is engaged, as I have been, on a large programme of work on the parallaxes of the fixed stars, or on observations to determine the distance of the sun by observations of minor planets.

I will not speak now of these researches, because they are still in process of execution or of reduction. I would rather, in the first place, endeavour to complete the picture of a night's work in a modern observatory.

We pass on to celestial photography, where astrometry and astrophysics join hands. Here on the screen is the interior of one of the new photographic observatories, that at Paris. [Brief description.]

Here is the exterior of our new photographic observatory at the Cape. Here is the interior of it, and the instrument. [Brief description.]

The observer's work during the exposure is simply to direct the telescope to the required part of the sky, and then the clockwork *nearly* does the rest—but not quite so. The observer holds in his hand a little electrical switch with two keys; by pressing one key he can accelerate the velocity of the driving-screw by about 1 per cent., and by pressing the other he can retard it 1 per cent. In this way he keeps one of the stars in the field always perfectly bisected by the cross-wires of his guiding telescope, and thus corrects the small errors produced partly by changes of refraction, partly by minute unavoidable errors in cutting the teeth of the arc into which the screw of the driving-shaft of the clockwork gears.

The work is monotonous rather than fatiguing, and the companionship of a pipe or cigar is very helpful during long exposures. A man can go on for a watch of four or five hours very well, taking plate after plate, exposing each, it may be, forty minutes or an hour. If the night is fine, a second observer follows the first, and so the work goes on the greater part of the night. Next day he develops his plate, and gets something like this. [Star-cluster.]

Working just in this way, but with the more humble apparatus which you see imperfectly in the picture now on the screen, we have photographed at the Cape during the past six years the whole of the southern hemisphere from 20° of south declination to the South Pole.

The plates are being measured by Prof. Kapteyn, of Groningen, and I expect that in the course of a year the whole work, containing all the stars to 9½ magnitude (between 200,000 and 300,000 stars) in that region, will be ready for publication. This work is essential as a preliminary step for the execution in the southern hemisphere of the great work inaugurated by the Astrophotographic Congress at Paris in 1887, the last details of which were settled at our meeting at Paris in April last. What we shall do with the new apparatus, perhaps I may have the honour to describe to you some years hence, after the work has been done.

We now come to an important class of astronomical work, more purely astrophysical, for the illustration of which I can no longer appeal to the Cape, because I regret to say that we are not yet provided with the means for its prosecution. I refer to the use of the spectroscope in astronomy, and especially to the latest developments of its use for the accurate measurement of the velocity of the motions of stars in the line of sight.[1]

It is beyond the province of this lecture to enter into history, but it is impossible not to refer to the fact that the chief impulse to astronomical work in this direction was given by Dr. Huggins, our Chairman to-night—nay, more, except for the early contributions of Fraunhofer to the subject, Dr. Huggins certainly is the father of sidereal spectroscopy, and that not in one but in every branch of it. He has devised the means, pointed the way, and, whilst in many branches of the work he still continues to lead the way, he has of necessity left the development of other branches to other hands.

From an astronomer's point of view the most important advance that has been made in spectroscopy of recent years is the sudden development of precision in the measures of star motion in the line of sight. The method remained for fifteen or sixteen years quite undeveloped from the condition in which it left the hands of Dr. Huggins, and certainly no progress in the accuracy attained by Dr. Huggins was made till the matter was taken up Dr. Vogel at Potsdam. At a single step Dr. Vogel has raised the precision of the work from that of observations in the days of Ptolemy to that of the days of Bradley—from the days of the old sights and pinnules to the days of telescopes. Therefore I take a Potsdam observation as the best type of a modern spectroscopic observation for description, especially as I have recently visited Dr. Vogel at Potsdam, and he has kindly given me a photograph of his spectroscope, as well as of some of the work done with it.

A photograph of the Potsdam spectroscope attached to the equatorial is now on the screen. [Description.]

The method of observation consists simply in inserting a small photographic plate in the dark slide, directing the telescope to the star, and keeping the image of the star continuously on the slit during an exposure of about an hour; and this is what is obtained on development of the picture.

If the star remained perfectly at rest between the jaws of the slit the spectrum would be represented by a single thread of light, and of course no lines would be visible upon such a thread; but the observer intentionally causes the star image to travel a little along the slit during the time of exposure, and so a spectrum of sensible width is obtained.

You will remark how beautifully sharp are the faint lines in this spectrum. Those who have tried to observe the spectrum of Sirius in the ordinary way, know that many of these fine lines cannot be seen or measured with certainty. The reason is that on account of irregularities in atmospheric refraction, the image of a star in the telescope is rarely tranquil, sometimes it shines brightly in the centre of the slit, sometimes barely in the slit at all, and the eye becomes puzzled and confused. But the photographic eye is not in the least disturbed; when the star image is in the slit, the plate goes on recording what it sees, and when the star is not in the slit the plate does nothing, and it is of no consequence whatever how rapidly these alternate appearances and disappearances recur. The only difference is that when the air is very steady and the star's image, therefore, always in the slit, the exposure takes less time than when the star is unsteady.

That is one reason why the Potsdam results are so accurate. And there are many other reasons besides, into which I cannot now enter. What, however, it is very important to note is this, that we have here a method which is to a great extent independent of the atmospheric disturbances which in all other departments of astronomical observation have imposed a limit to their precision. Accurate astrospectroscopy, therefore, may be pushed to a degree of perfection which is limited only by the optical aid at our disposal and by the sensibility of our photographic plates.

And now I think we have sufficiently considered the ordinary processes of astronomical observation to illustrate the character of the work of an astronomer at night. The picture should be completed by an account of his work by day; but to go into that matter in detail would certainly not be within the limits of this lecture. It is better that I should in conclusion touch upon some recent remarkable results of these day and night labours. It is these after all that most appeal to you; it is for these that the astronomer labours; it is the prospect of them that lightens the long watches of the night and gives life to the otherwise dead bones of mechanical routine.

Let us take first some spectroscopic results. To explain their meaning let me remind you for a moment of the familiar analogy between light and sound.

The pitch of a musical note depends on the rapidity of the vibrations communicated to the air by the reed or string of the musical instrument that produces the note, a low note being given by slow vibrations and a high one by quick vibrations.

Just in the same way red light depends on relatively slow vibrations of ether, and blue or violet light on relatively quick vibrations. Well, if there is a railway train rapidly approaching one, and the engine sounds its whistle, more waves of sound from that whistle will reach the ear in a second of time than would reach the ear were the train at rest. On the other hand, if the train is travelling at the same rate *away* from the observer, fewer waves of sound will reach his ears in a second of time. Therefore an observer beside the line should observe a distinct change of pitch in the note of the engine whistle as the train passes him, and as a matter of fact such a change of pitch can be and has been observed.

Just in the same way, if a source of light could be moved rapidly enough towards an observer it would become bluer, or if away from him it would become more red in colour. Only it would require a change of velocity in the moving light of some thousands of miles per second in order to render the difference of colour sensible to the eye. The experiment is, therefore, not likely to be frequently shown at this lecture table!

But the spectroscope enables such changes of colour to be measured with extreme precision. Here on the screen is the most splendid illustration of this that exists at present, viz. copies of three negatives of the spectrum of α Aurigæ, taken at Potsdam in October and December of 1888, and in March 1889.

The black line (the picture being a negative) represents the bright line $H\gamma$ given by the artificial light of hydrogen, the strong white line in the picture corresponds to the black absorption line which is due to hydrogen in the atmosphere of the star.

Why is it that the artificial hydrogen line does not correspond with the stellar line in all these pictures? The answer is, either the star is moving towards or from the earth in the line of sight, or the earth is moving from or towards the star. But in December the earth in its motion round the sun is moving at right angles to the direction of α Aurigæ; why then does not the stellar hydrogen line agree in position with the terrestrial hydrogen line? The simple explanation is that α Aurigæ is moving with respect to the sun.

---

[1] The older methods enabled us to measure motions at right angles to the line of sight, but till the spectroscope came we could not measure motions in the line of sight.

In what way is it moving? Well, that also is clear; the stellar line is displaced towards the red end of the spectrum—that is to say, the star light is redder than it should be in consequence of a motion of recession; this proves that the star is moving away from us, and measures of the photograph show the rate of this motion to be 15½ miles per second. We also know that in October the earth, in its motion round the sun, is moving towards α Aurigæ nearly at the same rate as we have just seen that α Aurigæ is running away from the sun. Consequently, at that time, their relative motions are nearly insensible, because both are going at the same rate in the same direction, and we find accordingly in October that the positions of the stellar and artificial hydrogen lines perfectly correspond. Finally, in March, the earth, in its motion round the sun, is moving away from α Aurigæ, and as α Aurigæ is also running away from the sun, the star-light becomes so much redder than normal that the stellar hydrogen line is shifted completely to one side of the hydrogen and artificial line.

The accuracy of these results may be proved as follows:—

If we measure all the photographs of α Aurigæ which Dr. Vogel has obtained, we can derive from each a determination of the relative velocity of the motion of the star with respect to our earth.

Of course these velocities are made up of the velocity of motion of α Aurigæ with respect to the sun (which we may reasonably assume to be a uniform velocity) and the velocity of the earth due to its motion round the sun. But the velocity of the earth's motion in its orbit is known with an accuracy of about one five-hundredth part of its amount, and therefore, within that accuracy, we can allow precisely for its effect on the relative velocity of the earth and α Aurigæ. When we have done so we get the following results for the velocity of the motion of α Aurigæ with respect to the sun. You see by the following table how beautifully they agree in the Potsdam results, and how comparatively rough and unreliable are the results obtained by the older method at Greenwich:—

α *Aurigæ—Potsdam.*

Date.	Observed relative motion of earth and star. Miles per sec.	Motion of earth.	Concluded motion. Star relative to the sun.
1888.

I believe that in a few years—at least, in a period of time that one may hope to see—we shall not be content merely to correct our results for the motion of the earth in its orbit only, and so test our observations of motion in the line of sight, but that we shall have arrived at a certainty and precision of working which will *permit the process to be reversed*, and that we shall be employing the spectroscope to determine the velocity of the earth's motion in its orbit, or, in other words, to determine the fundamental unit of astronomy, the distance of the sun from the earth.

I will take as another example one recent remarkable spectroscopic discovery.

Miss Maury, in examining a number of photographs of stellar spectra taken at Harvard College, discovered that in the spectrum of β Aurigæ certain lines doubled themselves every two days, becoming single in the intermediate days. Accurate Potsdam observations confirmed the conclusion.

The picture on the screen shows the spectrum of β Aurigæ photographed on November 22 and 25 of last year. In the first the lines are single; in the other every line is doubled. Measures and discussion of a number of these photographs have shown that the doubling of the lines is perfectly accounted for by the supposition of two suns revolving round each other in a period of four days, each moving at a velocity of about 70 miles a second in its orbit.

When one star is approaching us and the other receding, the lines in the spectrum formed by the light of the first star will be moved towards the blue end of the spectrum, those in the spectrum of the second star towards the red end of the spectrum. Then, as the two stars come into the same line with us, their motions become at right angles to the line of sight, and their two spectra, not being affected by motion, will perfectly coincide; but then, after the stars cross, their spectra again separate in the opposite direction, and so they go on.

Thus by means of their spectra we are in a position to watch and to measure the relative motions of two objects that we can never see apart—nay more, we can determine not only their period of revolution, but also the velocity of their motions in their orbits. Now, if we know the time that a body takes to complete its revolution, and the velocity at which it moves, clearly we know the dimensions of its orbit; and if we know the dimensions of an orbit we know what attractive force is necessary to compel the body to keep in that orbit, and thus we are able to weigh these bodies. The components of β Aurigæ are two suns, which revolve about each other in four days; they are only between 7 and 8 millions of miles (or one-twelfth of our distance from the sun) apart, and if they are of equal weight they each weigh rather over double the weight of our sun.

I have little doubt that these facts do not represent a permanent condition, but simply a stage of evolution in the life-history of the system, an earlier stage of which may have been a nebular one.

Other similar double-stars have been discovered both at Potsdam and at Cambridge, U.S., stars that we shall never see separately with the eye aided by the most powerful telescope; but time does not permit me to enter into any account of them.

I pass now to another recent result that is of great cosmical interest.

The Cape photographic star charting of the southern hemisphere has been already referred to. In comparing the existing eye-estimates of magnitude by Dr. Gould with the photographic determinations of these magnitudes, both Prof. Kapteyn and myself have been greatly struck with a very considerable systematic discordance between the two. In the rich parts of the sky—that is, in the Milky Way—the stars are systematically photographically brighter by comparison with the eye-observations than they are in the poorer part of the sky, and that not by any doubtful amount, but by half or three-fourths of a magnitude. One of two things was certain—either that the eye-observations were wrong, or that the stars of the Milky Way are bluer or whiter than other stars. But Prof. Pickering, of Cambridge, America, has lately been making a complete photographic review of the heavens, and, by placing a prism in front of the telescope, he has made pictures of the whole sky like this. [Here two examples of the plates of Pickering's spectroscopic *Durchmusterung* were exhibited on the screen.] He has discussed the various types of the spectra of the brighter stars, as thus revealed, according to their distribution in the sky. He finds thus that the stars of the Sirius type occur chiefly in the

Milky Way, whilst stars of other types are fairly divided over the sky.

Now, stars of the Sirius type are very white stars, very rich, relative to other stars, in the rays which act most strongly on a photographic plate. Here, then, is the explanation of the results of our photographic star-charting and of the discordance between the photographic and visual magnitudes in the Milky Way.

The results of the Cape charting further show that it is not alone to the brighter stars that this discordance extends, but it extends also, though in a rather less degree, to the fainter stars of the Milky Way. Therefore, we may come to the very remarkable conclusion that the Milky Way is a thing apart, and that it has been developed perhaps in a different manner, or more probably at a different and probably later epoch, from the rest of the sidereal universe.

Here is another interesting cosmical revelation which we owe to photography.

You all know the beautiful constellation Orion, and many in this theatre have before seen the photograph of the nebula which is now on the screen, taken by Mr. Roberts.

Here is another photograph of the same object, taken with a much longer exposure. You see how over-exposed, in fact burnt out, the brightest part of the picture is, and yet what a wonderful development of faint additional nebulous matter is revealed.

But I do not think that many persons in this room have seen *this* picture, and probably very few have any idea what it represents. It is from the original negative taken by Prof. Pickering, with a small photographic lens of short focus, after six hours' exposure in the clear air of the Andes, 10,000 feet above sea-level.

The field embraces the three well-known stars in the belt of Orion, on the one hand, and β Orionis (Rigel) on the other. You can hardly recognize these great white patches as stars; their ill-defined character is simply the result of excessive over-exposure. But mark the wonders which this long exposure with a lens of high intrinsic brilliancy of image has revealed. Here is the great nebula, of course terribly over-exposed; but note its wonderful fainter ramifications. See how the whole area is more or less nebulous, and surrounded as it were with a ring fence of nebulous matter. This nebulosity shows a special concentration about β Orionis.

Well, when Prof. Pickering got this wonderful picture, knowing that I was occupied with investigations on the distances of the fixed stars, he wrote to ask whether I had made any observations to determine the distance of β Orionis, as it would be of great interest to know, from independent evidence, whether this very bright star was really near to us or not. It so happens that the observations were made, and their definitive reduction has shown that β Orionis is really at the same distance from us as are the faint comparison stars. β Orionis is, therefore, probably part and parcel of an enormous system in an advanced but incomplete state of stellar evolution, and that what we have seen in this wonderful picture is all a part of that system.

I should explain what I mean by an elementary or by an advanced state of stellar evolution. There is but one theory of celestial evolution which has so far survived the test of time and comparison with observed facts, viz. the nebular hypothesis of Laplace. Laplace supposed that the sun was originally a huge gaseous or nebulous mass, of a diameter far greater than the orbit of Neptune. I say *originally*—do not misunderstand me. We have finite minds; we can imagine a condition of things which might be supposed to occur at any particular instant of time however remote, and at any particular distance of space however great, and we may frame a theory beginning at another time still more remote, and so on. But we can never imagine a theory beginning at an infinite distance of time or at an infinitely distant point in space. Thus, in any theory which man with his finite mind can devise, when we talk of *originally* we simply mean at or during the time considered in our theory.

Now, Laplace's theory begins at a time, millions on millions of years ago, when the sun had so far disentangled itself from chaos, and its component gaseous particles had by mutual attraction so far coalesced, as to form an enormous gaseous ball, far greater in diameter than the orbit of the remotest planet of our present system. The central part of this ball was certainly much more condensed than the rest, and the whole ball revolved. There is nothing improbable in this hypothesis. If gaseous matter came together from different parts of space, such coalition would unquestionably occur, and as in the meeting of opposite streams of water or of opposite currents of wind, vortices would be created, and revolution about an axis set up, such as we are familiar with in the case of whirlpools or cyclones. The resultant would be rotation of the whole globular gaseous mass about an axis.

Now this gaseous globe begins to cool, and as it cools it necessarily contracts. Then follows a necessary result of contraction, viz the rotation becomes more rapid. This is a well-known fact in dynamics, about which there is no doubt. Thus, the cooling and the contracting go on, and, simultaneously, the velocity of rotation becomes greater and greater. At last the time arrives when, for the outside particles, the velocity of rotation becomes such that the centrifugal force is greater than the attractive force, and so the outside particles break off and form a ring. Then, as the process of cooling and contraction proceeds still further, another ring is formed, and so on, till we have, finally, a succession of rings and a condensed central ball. If from any cause the cooling of any of these rings does not go on uniformly, or if some of the gaseous matter of the ring is more easily liquefied than others, then probably a single nucleus of liquid matter will be formed in that ring, and this nucleus will finally, by attraction, absorb the whole of the matter of which the ring is composed—at first as a gaseous ball with a condensed nucleus, and this will finally solidify into a planet. Or, meanwhile, this yet unformed planet may repeat the history of its parent sun. By contraction, and consequent acceleration of its rotation, it may throw off one or more rings, which in like manner condense into satellites like our moon, or those of Jupiter, Saturn, Uranus, or Neptune. Such, very briefly outlined, is the celebrated nebular hypothesis of Laplace. No one can positively say that the hypothesis is true, still less can anyone say that it is untrue. Time does not permit me to enter into the very strong proofs which Laplace urged in favour of its acceptance.

But I beg you for one moment to cast your imaginations back to a period of time long antecedent to that when our sun had begun to disentangle itself from chaos, and when the fleecy clouds of cosmic stuff had but commenced to rush together. What should we see in such a case, were there a true basis for the theory of Laplace? Certainly, in the first place, we should have a huge whirlpool or cyclone of cosmic gaseous stuff, the formation of rings, and the condensation of these rings into gaseous globes.

Remembering this, look now on this wonderful photograph of the nebula in Andromeda, made by Mr. Roberts. In the largest telescopes this nebula appears simply as an oval patch of nearly uniform light, with a few dark canals through it, but no idea of its true form can be obtained, no trace can be found of the significant story which this photograph tells. It is a picture that no human eye, unaided by photography, has ever seen. It is a true picture drawn without the intervention of the hand of fallible man, and uninfluenced by his bias or imagination. Have we not here, so at least it seems to me, a picture of a very early stage in the evolution of a star-cluster or sun-system—a phase in the history of another star-system similar to that which once occurred in our own—millions and millions of years ago, when our earth, nay, even our sun itself, "was without form and void," and "darkness was on the face of the deep."

During this lecture I have been able to trace but very imperfectly the bare outlines of an astronomer's work in a modern observatory, and to give you a very few of its latest results—results which do not come by chance, but by hard labour, and to men who have patience to face dull daily routine for the love of science—to men who realize the imperfections of their methods, and are constantly on the alert to improve them.

The mills of the astronomer grind slowly, and he must be infinitely careful and watchful if he would have them, like the mills of God, to grind exceeding small.

I think he may well take for his motto these beautiful lines—

> "Like the star
> Which shines afar,
> Without haste,
> Without rest,
> Let each man wheel
> With steady sway,
> Round the task
> Which rules the day,
> And do his best."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 12.—M. Duchartre in the chair.—On the theory of the antagonism of visual fields, by M. A. Chauveau.—An apparatus for carrying out various experiments connected with the study of binocular contrast, by the same author. The instrument described is that used by M. Chauveau in the experiments the results of which were communicated to the Academy on September 7 and 21. In the main it consists of a stereoscope having arrangements by means of which exact equality of luminous impressions may be realized, and the colours of the two fields altered independently.—New *réseau* of isotherms for carbonic acid, by M. E. H. Amagat. The author has determined the isotherms of carbonic acid for every 10° from 0° to 100°, and also those corresponding to 32°, 35°, 137°, 198°, and 258°; the pressures having been taken up to 1000 atmospheres. The results obtained are graphically shown in the accompanying figure, in which the abscissæ represent pressures, and products of P × V furnish the ordinates.—Variation of the composition of Jerusalem artichokes at different periods of their growth; *rôle* of the leaves, by M. G. Lechartier. Analyses of the dried black leaves which appear on Jerusalem artichokes in the autumn have been made, and the results compared with analyses of green and yellow leaves. The effect of different fertilizers on their composition has also been studied. It appears that the black leaves must have had the same composition as the green leaves, and the substances which they lose are utilized for the nutrition of the higher leaves of the plants. They preserve their vitality as long as the soil furnishes the plant with sufficient phosphoric acid and potash. But if either of these fertilizers be absent, the leaves begin to dry up.—Observations of Tempel-Swift's periodic comet, made at Paris Observatory with the West Tower equatorial, by M. G. Bigourdan. Observations for position were made on October 8 and 9. It is remarked: "The comet is an excessively feeble nebulosity, at the extreme limit of visibility: it is round, from 1'·5 to 2' in diameter, and slightly brighter towards the centre."—Observations of the same comet, made at Paris Observatory with the East Tower equatorial, by Mdlle. D. Klumpke. An observation for position was made on October 9.—Experimental researches on "personal equation" in transit observations, by M. P. Stroovant. The author has determined his "personal equation" for observations of stellar points and disks under different conditions of illumination of the field of the telescope employed. His equation was very different when the preceding edge was observed to transit than when the passage of the following edge was noted. It was also subject to a slight variation. Observations by the "eye and ear method" show a tendency to choose certain tenths of a second in preference to others.—On conjugate systems and on the deformation of surfaces, by M. E. Cosserat.—On turbo-machines, by M. Rateau.—Variation of the electromotive force of piles with pressure, by M. Henri Gilbault. Taking the formula $q\frac{dE}{dp} = dv$, in which E = electromotive force, q the quantity of electricity developed and producing a variation of volume v, and p the pressure, the author has calculated the variations of the electromotive force of different piles, and finds that the results agree extremely well with those arrived at experimentally up to a pressure of 100 atmospheres.—A multitubular electric accumulator, by M. D. Tommasi.—Calculation of the specific heats of liquids, by M. G. Hinrichs.—Melting-point of certain binary organic systems, by M. Léo Vignon.—Calorimetric researches on the state of silicium and aluminium in cast-irons, by M. F. Osmond.—Heat of formation of platinic bromide and of its principal compounds, by M. Léon Pigeon.—Contribution to the study of hematozoaires; on the hematozoaires of the frog, by M. Alphonse Labbe.

COPTIC PALÆOGRAPHY.

Album de Paléographie Copte pour servir à l'Introduction Paléographique des "Actes des Martyrs de l Égypte." Par Henri Hyvernat. (Paris: Leroux, 1888.)

IN all the wide range of subjects connected with archæology, it would perhaps be difficult to find one so little studied as that the name of which stands at the head of this article. It is not that it is unimportant; on the contrary, it is most important; it cannot be said to be uninteresting, for the most elementary study of the subject shows it to possess considerable attractions for the philologist, historian, and antiquary. The little interest which, until the last few years, has been shown in matters relating to the Coptic language and literature is probably to be attributed to the fact that printed Coptic texts are scarce, and that the comparatively few manuscripts which exist are scattered throughout the libraries of Europe.

It will be remembered that in the year 1885 M. Hyvernat began to publish the martyrdoms of famous Coptic saints, with a translation in French entitled "Les Actes des Martyrs de l'Égypte"; the Coptic texts were edited chiefly from manuscripts in the Vatican and Borgian Libraries. Considerable interest was aroused by his work, and it was hoped that scholars would soon possess accurate copies of the texts of the martyrdoms which form so large a section of the rich collections of Coptic manuscripts at Rome. It may be argued that the narratives of the sufferings and deaths of Coptic martyrs have much in common, and that a few examples of this class of literature would have been sufficient; but it must be remembered that the historical allusions and incidental remarks made in them give them a value far beyond their importance as religious documents; while the uncommon words, and unusual forms of the Greek words which their writers borrowed, enrich the Coptic lexicon, and afford material for the student of hieroglyphics who makes a comparative study of the dialects spoken by the Copts and by their ancestors the subjects of the Pharaohs. The first volume of the work, in four fasciculi, has appeared, and it is hoped that the second volume, which is promised to contain a critical introduction, &c., will not be long delayed.

Meanwhile, however, M. Hyvernat has given us his "Palæographic Album," and it is to this important publication that we must now give our attention; the scientific plan which he has followed in setting before scholars facts and nothing but facts, and his systematic arrangement of them, make his work most welcome. The first Coptic scholar who gave his attention to the subject of Coptic palæography was Zoega, the Dane, and in his famous "Catalogus Codicum Copticorum," published (after his death) at Rome in 1810, are given seven plates containing specimens of the writing found in Coptic manuscripts of various periods; since that time *facsimile* specimens of important manuscripts have been published, as, for example, a page of the famous Gnostic work, "Pistis Sophia," in the "Facsimiles of Ancient Manuscripts, &c.," issued by the Palæographical Society (Oriental Series, plate 42, 1878).

The work before us contains fifty-seven large folio plates, upon which are reproduced by photography about one hundred examples of Coptic writing; the execution of these plates is perfect, and M. Hyvernat has shown great knowledge and judgment in making the selection. The original manuscripts are preserved in Rome, Milan, Turin, Naples, Paris, London, and Oxford; and the time and labour spent by him in reading and examining them must have been very considerable. The manuscripts—that is, books made of parchment and paper, for M. Hyvernat excludes inscriptions upon stones, and papyri, whether contracts or otherwise—belong to all periods; the earliest cannot be later than the sixth century A.D., and the latest dates from the last century. We have thus for palæographical investigation a field of not less than twelve hundred years.

The specimens of the writings anterior to the ninth century have been taken from manuscripts which are, by the common consent of the best authorities, admitted to belong to this period; all those after the ninth century are taken from dated manuscripts, and thus there is no doubt possible as to their age. The wisdom of this plan is evident, for, in the case of uncial writing, the character of which practically remained unchanged among the Copts for centuries, it is almost impossible to assign an exact date to a manuscript unless a dated standard is forthcoming. Coptic manuscripts which are to be attributed to the sixth or seventh century are rare, and as examples of them M. Hyvernat has selected the Gnostic treatise called "Pistis Sophia"[1] (Brit. Mus., No. 5114) and the life of St. Pachomius;[2] the pages are small quarto in size, with two columns of writing to the page, and ornamentation is rare. In the seventh and eighth centuries the writing becomes firmer and bolder, the pages are larger, and the sides of the columns are ornamented with graceful designs and birds (doves?). The picture of Job and his three daughters (Pl. 5), wearing Byzantine costumes and ornaments, is very instructive. Pl. 6 gives a leaf from a palimpsest manuscript, inscribed in Coptic with verses from the Old Testament, and in Syriac with the martyrdom of St. Peter of Alexandria.

Of the tenth and eleventh centuries we have fine specimens of manuscripts containing homilies, canons, sermons, martyrdoms, &c.; the pages are large, the writing, in two columns, is bold and handsome, the initial letters of paragraphs are large, and stand away from the columns, which are often profusely decorated with birds, flowers, ornaments in the shape of vases, &c. The last pages of works of this period often contain portraits of those who are referred to in them, and the larger manuscripts have full-page illustrations of the subject-matter; as, for example, Theodore the General overthrowing the dragon and rescuing the widow's children (Pl. 16), St. Mercurius destroying Julian the Apostate (Pl. 17), and "Moses the Prophet" standing with bare feet by the side of the burning bush (Pl. 19). On Pls. 14, 21, and 32 are some interesting examples of Coptic cryptography and cursive writing. At the end of the tenth century the first page of each work in a manuscript is ornamented with deep borders of tracery and interlacing in various colours, and the initial letters are very large (Pls. 34, 38).

---

[1] The text, with Latin translation, was published by Schwartze at Berlin in 1851.

[2] The text, with French translation, was published by Amélineau, "Histoire de Saint Pakhôme" (Paris, 1889).

A fine example of the writing and illumination of the thirteenth century is that given on Pl. 1, from a Coptic and Arabic Evangelarium written A.D. 1250; in it St. Mark, seated, is about to receive in a napkin the book of the Gospels from St. Peter, and by his side is a stand in the shape of that used to hold a Koran; opposite is a scene in which John the Baptist is baptizing Christ in the Jordan, in the presence of two angels, who hold napkins, and above them is descending from blue heavens the Holy Ghost in the form of a dove. Behind John the Baptist is a tree, in the trunk of which an axe has been struck. Of illustrated Gospels of this period we have excellent specimens on Pls. 44–47, where the Transfiguration, the devils entering the swine, the Marriage at Cana, the Last Supper, the Crucifixion, &c., display a quaint mixture of ancient Coptic, Byzantine, and Arab methods of illumination and ornamentation. Of manuscripts of the thirteenth and fourteenth centuries good examples are given on Pls. 50 foll., with *facsimiles* of the elaborate crosses of the period and of the portraits of the four Evangelists in circles. The space at our disposal will not allow a more detailed description of the contents of the "Album de Paléographie Copte" than that given above, which will serve to indicate the great value of the work to scholars.

The Copts, or "Egyptian" Christians, played no unimportant part in the history of Egypt after the preaching of St. Mark at Alexandria, A.D. 64; and from that time until the present day they have steadily and consistently maintained their religious opinions without change. They clung fast to their language, in spite of the widespread use of Greek in Egypt in the earlier centuries of this era; and although they adopted the Greek alphabet, with the addition of some few signs from the demotic, and borrowed largely from the Greek vocabulary, they did not cease to write their books in Coptic nor to celebrate the services of their Church in that language. After the conquest of Egypt by the Arabs, the Copts held positions of dignity and importance there for some hundreds of years; but about the twelfth century they seem to have fallen into poverty and contempt, and about a century later it seems that they ceased to produce literary works; moreover, the growing custom of adding Arabic translations by the side of the Coptic texts proves that the knowledge of Coptic was dying out. During the next few centuries it probably became the study of the learned. In the course of the last two centuries, travellers in the East have brought to Europe numbers of Coptic manuscripts, and among those deserving special mention are Pietro della Valle, and Huntingdon, Assemani, Curzon, and Tattam. The revival of Coptic learning was begun by Abela, a Maltese; and his work was carried on by Kircher, Petræus, Jablonski, Renaudot, Wilkins, Vansleb, Lacroze, Tuki, George, Zoega, Quatremère, Tattam, and Peyron: among those who have done much excellent work in Coptic during the present century are Schwartze, Lagarde, Revillout, and Rückert. The recent works of Amélineau and Hyvernat show that serious attention is now being paid to the Coptic language for philological and ecclesiastical purposes, and that the publication of new material is going on rapidly.

In conclusion, all lovers of Coptic literature owe a debt of gratitude to M. Henri Hignard, formerly President of the Académie de Lyon, for his liberality in undertaking the expense of publishing this work, and to M. Hyvernat for the excellent way in which he has made use of the funds so generously placed at his disposal.

BRITISH MUSEUM (NATURAL HISTORY) CATALOGUES.

Systematic List of the Frederick E. Edwards Collection of British Oligocene and Eocene Mollusca in the British Museum (Natural History); with References to the Type Specimens from similar Horizons contained in other Collections belonging to the Geological Department of the Museum. By Richard Bullen Newton, F.G.S. Pp. xxviii. and 365, with a large Folding Table. (London: Printed by order of the Trustees. Sold by Longmans and Co.; Quaritch; Dulau and Co.; Kegan Paul, Trench, Trübner, and Co.; and at the Natural History Museum. 1891.)

THE interest which attaches to the records of past periods of our earth's history is greatly enhanced when we find them in the strata forming the very ground beneath our feet. Such is the explanation of the origin of the well-known Edwards Collection of Eocene Mollusca, which forms the subject of the volume before us. Mr. Frederick Edwards resided at Hampstead some fifty years ago, at a time when the Primrose Hill tunnel of the London and North-Western Railway was formed, and the Archway Road, Highgate, had lately been cut, and, later still, the Great Northern tunnel under Copenhagen Fields. These, and many brick-field excavations in the north of London, led to the discovery of abundant fossil-remains around his residence, and attracted the attention not only of Mr. Edwards, but of Dr. Bowerbank, Mr. Wetherell, Prof. John Morris, Mr. Searles V. Wood and his son, Mr. Sowerby, Mr. White, Mr. Page, and other geologists living in Highbury, Highgate, Hampstead, and Kentish Town, who formed among themselves a small Naturalists' Society, known as the "London Clay Club," the members of which met periodically at each other's houses, to compare and exchange specimens, and to name the fossils they had discovered in the London clay. Mr. Wetherell, Dr. Bowerbank, and Mr. Frederick Edwards made most extensive collections; but, whilst Wetherell and Bowerbank collected from the London Clay, the Chalk, and other formations, Mr. Frederick Edwards devoted all his attention to the Mollusca of the London Clay and other Tertiary beds of the south-east of England. All his summer holidays were spent in such spots as the New Forest (where, at Brockenhurst, Bramshaw, Lyndhurst, and many other spots, assisted by Mr. Henry Keeping, he opened numerous trial-pits), or at Barton and Hordwell on the coast of Hampshire, Colwell Bay, Headon Hill, Osborne, Hempsted, Bembridge in the Isle of Wight, and Bracklesham Bay, Sussex. He collected at all these places, and *carefully recorded* the localities from whence his specimens were derived. With infinite care he mounted and named these delicate Tertiary shells, and the beautiful specimens so prepared have been preserved in their entirety in the National Museum.

After the formation of the Palæontographical Society, a large number of Mr. Edwards's Mollusca were monographed by him from 1849 to 1860 (five parts), and continued by S. V. Wood, 1861 to 1877 (four parts); and papers were published in the *London Geological Journal*, the *Geologist*, the *Geological Magazine*, and the Quarterly Journal of the Geological Society of London.

The unpublished labour which Mr. Edwards expended on his cabinets greatly exceeded that which he devoted to the publication of a part of their contents, as may readily be seen by a study of his collection; and when it is known that this work was all performed in the leisure hours of a busy life as a Master-in-Chancery, hearing and deciding law cases in Chambers all day, one is astonished to find how much he was able to accomplish.

The collection contains no fewer than 39,191 specimens, referred to 1805 species of Mollusca, divided into the following classes:—

85	genera and	648	species of	Lamellibranchiata,
162	,,	1127	,,	Gasteropoda,
2	,,	14	,,	Scaphopoda,
6	,,	16	,,	Cephalopoda.
		1805		

Of this number 585 are manuscript species, proposed by F. E. Edwards, which have not yet been described; so that nearly one-third has to be deducted from the above total if we would arrive at the actual number of species already figured and described.

It may be objected that these manuscript names ought not to have been printed; but Mr. Newton points out, in the preface to his catalogue, that these have got into circulation abroad in lists published by German and French palæontologists, with whom Mr. Edwards had corresponded, until, like some paper-currencies, they have obtained for themselves an artificial value, and it would be inconvenient to omit to mention them in a list of Mr. Edwards's own collection. Mr. Newton, moreover, promises shortly to describe and figure them, thus giving them their full *specie-value*, a promise which we sincerely trust he will find leisure to perform.

In addition to the specimens in F. E. Edwards's own collection, figured and described by himself and others, all those in the Brander, Sowerby, Dixon, Bowerbank, and Wetherell collections are duly recorded; so that much valuable information as to the whereabouts of these types, and references to the works in which they are recorded, has been carefully brought together in this volume by Mr. Newton.

Apart from the vast variety, as well as the rare beauty of form, by which the Mollusca of the Eocene period at once arrest the attention of even the most unlearned, to the student of palæontology they afford unmistakable evidence of the existence in this earliest Tertiary period of subtropical marine conditions over this portion of the earth's surface, which now forms South-eastern England. Several extinct forms of Nautilus and Cuttlefishes, associated with huge species of *Cerithium*, Cowries, Cones, Volutes, and such genera as *Rostellaria*, *Mitra*, *Marginella*, *Cancellaria*, *Oliva*, *Ovula*, and *Seraphs*, with *Terebra*, *Pirenia*, *Phorus*, *Solarium*, *Nerita*, and *Chiton*, make up a rich display of Mollusca belonging to the warmer seas of the globe, and if we add such genera as *Pholadomya*, *Spondylus*, *Crassatella*, and many of the other bivalves, they tell the same tale. Crustacea, Echinodermata, and Corals were also present, together with numerous Turtles, whilst along the shores of the rivers huge Crocodiles patiently awaited the *Palæotheria* and *Anoplotheria* from the neighbouring lands. Terrestrial vegetation, washed down from the Eocene continent, also proves to be of a tropical kind —Palms, Cacti, Dryandra, Maple, Azalea, Acacias, with others, belonging to more temperate latitudes, forming a part of the vegetation of our island to-day. Nor were the terrestrial Mollusca unaffected by the increased temperature, for we find large *Bulimi* and *Helices* unlike those now living in this country, whilst the species of *Limnea* and *Planorbis* were both large and very abundant, and were associated with *Potamides*, *Melania*, and other exotic genera in its streams. That there must have been at that time a close connection between our English Eocene area and the much larger Eocene area of France, cannot be doubted, for the beds of the Paris basin and those of Hampshire and London are capable of close correlation, and many genera and species are common to both areas.

Mr. Newton has fortunately obtained the co-operation of Mr. George F. Harris, who has, in an appendix, added some valuable tables, showing the probable equivalent horizons of our several English Tertiary beds with those on the Continent, in France, Belgium, and Germany, and as far east as Austria and Italy, and southwards to Spain. These tables will prove of the greatest value to the student who seeks to understand, and even to map out, the former geographical extent of the several successive Tertiary deposits of Europe, with their varied land, freshwater, and marine records of past life, both animal and vegetable.

Most of the points dealt with by Mr. Newton in the introduction to his list have reference to questions of priority in names, and explanatory notes in justification of some which have been abolished—either because the name had been pre-occupied for a genus of fishes, or birds, or reptiles, &c., or because it had been discovered that another author had previously described the same shell, and had at an earlier date given it another name. Many old favourites have thus been relegated to obscurity, whilst fresh names, dug up from some forgotten corner, have, by the law of priority, taken their places. Thus:—*Meretrix*, Lamarck, 1799, takes the place of his better known *Cytherea* of 1806, the latter having been applied by Fabricius, in 1805, to a dipterous insect. *Triton*, De Montfort, 1810, gives place to *Lampusia*, Schumacher, 1817, "having been applied by Linnæus to a Cirripede in 1767." But as no genus of Cirripedes is known by that name at present, this is a needless and undesirable alteration, especially as Mr. Newton remarks, "the genus *Triton* still continues a favourite name among conchologists"; we would add, "long may it continue" so. Darwin says: "I cannot doubt that the *Triton* described by Linnæus was only the *exuviæ* of some *Balanus* (probably *B. porcatus*), Linnæus mistaking the proboscidiformed penis for the mouth of his imagined distinct animal" (Darwin's *Balanidæ*, Ray Soc., 1854, p. 158).

It would be an immense gain if every name proposed to be altered had to pass through a regularly-constituted committee of investigation before it was accepted and allowed to pass current; as it is, endless confusion must arise, and needless alterations will for ever be made, serving no good end to science.

Mr. R. B. Newton's systematic list of the Eocene and Oligocene Mollusca of our British strata will prove extremely valuable to all those who take an interest in our Tertiary deposits and their contained organisms. Every curator of a palæontological collection must have it, as a work of reference, by his side, as, for this section of fossils, it takes the place of "Morris's Catalogue," now long out of date. We shall be very glad to see other sections treated in a similar manner—indeed, Messrs. A. Smith Woodward and C. D. Sherborn have already catalogued the fossil Vertebrata of the British Isles in 1890, and the work has been published by Dulau and Co.

THE LIFE AND WORK OF A NORFOLK GEOLOGIST.

Memorials of John Gunn: being some Account of the Cromer Forest Bed and its Fossil Mammalia. Edited by H. B. Woodward and E. T. Newton. Pp. xii, 120; 13 Plates (Portrait and Fossil Mammalia). (Norwich: W. A. Nudd, 1891.)

ALL students of the geology of the eastern and central parts of Norfolk and Suffolk will welcome this book, as giving the well-matured opinions of a geologist whose life-work was chiefly concerned with the Forest Bed and its associated formations, Crag and Drift. Those too who knew Mr. Gunn must be glad to have this memorial of so courteous, kindly, truth-seeking a man. No one enjoyed his friendship but was the better for it, and the writer looks back on days spent in his company, both in the field and at meetings of the Norwich Geological Society, as amongst the happiest events of a long sojourn in the Eastern Counties. Until reading this book he did not know the politics of Mr. Gunn, and he is glad to find another of many instances in which such matters are kept in the background, as regards scientific intercourse and personal friendship.

To those who, like the writer, are not greatly enamoured with biography and its multiplicity of personal details it is satisfactory to find this part of the book artistically treated, by Mr. Woodward, in only 27 pages, which are full of interest. The best memorial of a scientific man is the work that he has done and by which he will be known in the time to come, and it is to Mr. Gunn's work that the editors chiefly direct our attention. After the memoir and about 13 pages of notes on some of his geologic papers, the book takes the form of a short essay on the Cromer Forest Bed and its fossil Mammalia, by the hand of Mr. Gunn himself; that is to say, from notes practically completed by him shortly before his death.

For the task of bringing these matters before the public no better editors could have been chosen. One of them, who, in his Geological Survey work, was brought much in contact with Mr. Gunn, may be called the hereditary geologist of Norfolk. The other has for some years given great attention to the study of the fossil Mammalia of the Forest Bed, and indeed has made himself the chief authority on the subject.

In 1864, Mr. Gunn helped to found the Norwich Geological Society, of which he was the first and the last President, retiring from that post only for six years (1877–83) in order that it should be filled by officers of the Geological Survey who were stationed in Norfolk and Suffolk: a graceful compliment. He was also one of the founders of the Norfolk Archæological Society, an active member of the Norwich Science Gossip Club, and a member of the Norwich Museum, which he enriched by his fine collection of fossil mammals.

Now that coal has been found underground at Dover, and that there may be some chance of a search for it being made in the Eastern Counties, it should be remembered that Mr. Gunn was the first to advocate trial-work in Norfolk.

On the ground that "unanimity does not prevail in regard to the nomenclature of the strata" of the Norfolk cliffs, Mr. Woodward gives a useful table, on p. 40, showing the classifications of Gunn, of Prestwich, and of C. Reid; but that of Wood might have been added with advantage; and he draws attention to the fact that the cliffs are cut back greatly year by year, so that earlier observers may have seen something different from later ones. As the loss of coast is still going on, and the Forest Bed seems not to reach far inland, a happy time may come when that Series will cease to furnish any ground for contention: in this matter the geologists of the future may have to take the work of their foregoers, without the luxury of upsetting it.

In his account of the Forest Bed Series, Mr. Gunn holds to the view that, as a rule, the trees grew on the spots where the stumps are now found. He describes firstly the Estuarine Soil, then the Forest Bed proper, then the Reconstructed Forest Bed (a division not hitherto recognized, and hardly likely to be, reconstruction seeming to occur in various parts of the Series), and lastly the Unio and Rootlet Bed; but it should be noted that other observers take the Forest Bed and the Rootlet Bed to be one. His use of the term Laminated Beds, for the immediate successor of the Forest Bed Series, is unfortunate, as such names usually are, for lamination is common in the Chillesford Clay below and in some of the Glacial Drift above.

Mr. Gunn's notes conclude with remarks, in some detail, on the Proboscidea of the Norwich Crag and of the Forest Bed Series, and on the Cervidæ of the latter, chiefly based, with the plates, on the specimens which he so liberally gave to the Norwich Museum. The notes are followed by a list of his geological and archæological papers, ranging over forty-eight years, from 1840 to 1887.

The plates of Mammalian fossils are well executed; but it is a pity that those of Proboscidea and those of Cervidæ are not numbered consecutively, instead of independently. The portrait that forms the frontispiece is a good one, and the book is well printed.

Few geologists can expect their names to be handed down to posterity by so fine a set of specimens as those of the Gunn Collection in the Norwich Museum, and by so interesting a literary accompaniment as that now noticed.

W. W.

OUR BOOK SHELF.

The Melanesians: Studies in their Anthropology and Folk Lore. By R. H. Codrington, D.D. (Oxford: Clarendon Press, 1891.)

IN this book Dr. Codrington gives us the results of observations and inquiries made in the Melanesian Islands from 1863, when he first visited them, to 1887, when he left the Melanesian Mission. He does not profess to offer a complete account of the Melanesian people; nevertheless, the work is one of great value, for it is in the main a record, not of what Europeans say about the natives, but of what the natives say about themselves. The most careful of European inquirers may, of course, mistake the real significance of what natives tell them; but Dr. Codrington seems to have been at all times fully conscious of this danger, and to have done his best to guard against it.

He begins with a chapter on the discovery of the Melanesian Islands, and on their geology and zoology. The ethnology of Melanesia he does not attempt to deal with; but he discusses thoroughly the facts relating to kinship and marriage connection among the Melanesians, starting with the proposition that the division of the people into two or more classes, which are exogamous, and in which descent is traced through the mother, is the foundation of native society. He also gives a good account of the position of the chiefs. A chapter is devoted to property and inheritance, and this is followed by a description of secret societies and clubs, a knowledge of both of which is essential to a proper comprehension of Melanesian life.

The religion of the Melanesians, like that of all savage and barbarous peoples, is a subject of great difficulty; but Dr. Codrington is able to present clearly what seem to be at least its main outlines. Students of the evolution of religious conceptions will read with especial interest what he has to say about "mana," a supernatural power or influence which is supposed to act in all kinds of ways for good and evil, and which everyone tries to possess or control. The objects of worship are spirits, some of which were formerly men, while others belong to an independent and higher class. All these beings are full of "mana," and many suggestive facts about the popular belief in them will be found in the chapters on sacrifices, prayers, spirits, sacred places and things, magic, possession, and intercourse with ghosts. There are also good chapters on birth, childhood, and marriage; death, burial, and "after death."

The chapters on the arts of life, and on dances, music, and games, contain an immense number of interesting facts, well arranged; and in a chapter entitled "Miscellaneous," the author treats of several disconnected subjects, such as cannibalism, head-taking, and castaways. The concluding chapter is in some respects the best of all. It consists of stories, divided into three groups—animal stories, myths and tales of origins, and wonder tales. These stories are not only pleasant to read, but provide excellent materials for those who devote themselves to the comparative study of folk-tales.

We may note that there are some very good illustrations, especially in the chapter on the arts of life.

Guide to Examinations in Physiography, and Answers to Questions. By W. Jerome Harrison, F.G.S. (London: Blackie and Son, 1891.)

THE author of this little work of forty-eight pages is well known as a successful teacher, of wide experience in connection with classes recognized by the Science and Art Department. It is avowedly a guide to the art of passing an examination, the author giving it as his opinion that "knowledge of any subject is not the *only* requisite to successfully passing an examination in it." Unfortunately, this is, to a certain extent, true. Some candidates are apt to make an injudicious choice of questions, while others, again, spend too little time in studying them, and consequently wander from the point. Few who read Mr. Harrison's notes will fail to profit by the sound advice which he gives.

The first part gives general information about the Science and Art Department and its objects, and applies equally to all the subjects in which its examinations are held. The questions which have been given in the elementary stage since 1882 are answered in Part III. They appear to be sufficiently good to satisfy the examiners.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Difficulty in Weismannism.

WEISMANN'S theories of heredity and sexual reproduction have been criticized from many *a priori* points of view. The following remarks are an attempt to apply to his theory of reproduction a test familiar to the mathematician; and assuming its truth, to follow out the deductions from this assumption. The result is a startling one. I believe the following theses will be accepted as an impartial statement of the main points of the theory:—

I. Each primitive germ-cell, of either sex, contains a number of ancestral germ-units, the Ahnenplasmas; and this number is constant, for the species at least.

II. These ancestral germ-units are far more constant and unchangeable in character than the species itself.

III. They lie associated together in the germ-cell without loss or alteration of their individual personalities.

IV. The number contained in the mature ovum and spermatozoon is reduced by one-half; and in the fertilized ovum or oosperm the number is restored to the normal by the summation of the Ahnenplasmas of the two fusing cells. This process is comparable to the shuffling of two packs of cards by taking half from each and joining the talons or remainders to form a new pack.

V. The possible combinations under this process are so numerous as to explain the variations among the offspring of sexual union.

Accepting these statements, we next inquire, How are we to conceive of these ancestral units, the Ahnenplasmas? Two hypotheses may be given in answer to this question:—

A. Each Ahnenplasma unit corresponds to an individual of the species itself; and if put under proper trophic conditions would, singly, reproduce such an individual.

B. The Ahnenplasmas correspond to the primitive Protozoan ancestors, which, according to theory,[1] could alone reproduce modifications due to external causes (acquired modifications).

According to hypothesis *A*, the Ahnenplasmas of living man are Anthropic; those of our Simian forebears were Simian; and so we get Protochordate, and finally Protometazoan Ahnenplasmas in the germ-cells of our more and more remote ancestors. In other words, the *Ahnenplasms have varied indefinitely, and at the same rate with the race.* This inference not only renders the shuffling process unnecessary to explain variation; but it is inconsistent with thesis II., the very foundation of Weismann's theory of heredity.

According to hypothesis *B*, the Ahnenplasmas of all Metazoa being similar and Protozoan, if the *numbers are equal* and the shuffling fair any two parents may beget any offspring whatever; on the plane of thesis V., a lioness might be expected to bring forth a lobster or a starfish or any other animal, which, as we know, does not take place in Nature. The only escape from this result is to assume the postulates—(1) that the number of Ahnenplasmas varies from species to species; (2) that the *number* in the combination and not the *character* of the Ahnenplasmas determines the species. And as there is not a particle of evidence for the latter postulate, we may say that on hypothesis B the theory breaks down by its non-conformity with the facts.

---

[1] "Hereditary variability . . . can only arise in the lowest unicellular organisms; and . . . necessarily passed over into the higher organisms when they first appeared" (Weismann, "On Heredity," English edition, p. 279). This passage would seem to render hypothesis *B* necessary for the theory.

We have then the dilemma, from which I see no escape, that the theory is inconsistent, on A with itself, on B with the facts. When once worked out and fairly put into words, which was not so easy as it may appear, this argument seemed so obvious that I felt sure it must have been long since urged, confuted, and dismissed. But not having found any reference to it, I now state it fully, in the hope that the question raised may be thoroughly discussed. Marcus Hartog.

Dublin, October 12.

Rain-making Experiments.

Your last number contains an article by Prof. Curtis on the "rain-making" experiments in Texas, in which no reference is made to the report published in the October number of the *North American Review* by General Dyrenforth, who directed the operations. I wish to call attention to the remarkable differences which exist between the statements of Prof. Curtis, the meteorologist of the expedition, and General Dyrenforth, its director. On August 10, Prof. Curtis, who had not yet arrived at the scene of the experiments, believes that only sharp showers or "good grass-rain" fell; General Dyrenforth says the amount was nearly 2 inches. On August 18, Prof. Curtis says that only 0·02 inch of rain fell; General Dyrenforth says that "drenching rain fell in torrents for two and a half hours," and that driving from the encampment to Midland, a distance of 25 miles, the road traversed was covered for 6 or 8 miles under 4 to 40 inches of water. It is impossible, under these circumstances, for those interested to come to any conclusion at present with regard to the actual results of the experiments. May I draw your attention further to an article which appeared in the *Manchester Guardian* of the 13th inst., in which a suggestion was made precisely similar to that put forward by Prof. Giglioli in your last number. If, as seems probable, the experiments of Mr. Aitken amply suffice to explain any positive results obtained, it is evident that the explosions of hydrogen and oxygen, on which General Dyrenforth relies so much, are useless, and that the smoke-producing rackarock does all the work. In an extremely sceptical and very justly critical article, which follows that of General Dyrenforth in the *North American Review*, Prof. Simon Newcomb, while scouting the "concussion" theories of General Dyrenforth, says, indeed, that smoke particles may possibly serve as nuclei for the condensation of water vapour; but he is evidently unacquainted with the remarkable work of Mr. Aitken, which throws so much light on the matter. H.

Manchester, October 24.

A Rare Phenomenon.

Having just returned from Norway, it may be of interest to record that the band of light which was observed by many of your correspondents on September 11, was remarkably brilliant in N. lat. 62°, extending from the horizon to the zenith, but not beyond. It was nearly, but not quite, equal in width throughout the 90°, and therefore must either have been much wider at the base than at the apex, or else at an immense altitude. Some clue to the estimation of this altitude would be afforded by an accurate record of the zenith distance as observed in England.

I may add that the aurora borealis was distinctly visible in the north and north-west at the same time, but this band rose from the north-east, which led me to conjecture that it might belong to a comet; however, on the following night it did not recur, and I then thought it might have been caused by some sun-lit cirri at a great elevation, but it is now obvious that this was not the case. The remarkable feature was its concurrence with, and yet apparent difference from, the ordinary aurora.

Richmond, Surrey, October 24. W. Duppa-Crotch.

The phenomenon observed by Dr. Copeland (Nature, September 24, p. 494) at 11.18 p.m. on September 10 at Dunecht, by Mr. W. E. Wilson at 9 p.m. on September 11 in Co. Westmeath, and by other observers on the 11th in several parts of England, was observed by a party of three, including myself, at 9.30 p.m. on September 25 at Ballater, Aberdeenshire.

It appeared as an intense white beam of light stretching from east to west and directly overhead, of uniform width and perfectly steady. It seemed quite low down, almost as if it might light up the summit of the church spire were it moved a little further towards the south. At 11.30 the light had become diffuse, and it appeared at a much greater elevation, though maintaining its general direction from east to west. W. N. Hartley.

October 23.

Earthquake at Bournemouth.

We had a sharp momentary shock of earthquake here at four o'clock this afternoon. I happened to have my eyes fixed on a plant with long variegated leaves on my dining-room table. Suddenly there was a heavy sound as of some subterranean fall, and simultaneously the leaves of this plant were violently agitated—waved up and down—for some seconds. It was as if it had risen vertically and then fallen. It was wholly unmoved by so much as a tremor the rest of the afternoon. I tried to reproduce anything like the same disturbance by hand, but without success. Henry Cecil.

Bregner, Bournemouth, October 25.

$W = Mg$.

I had read Mr. Slate's letter (Nature, vol. xliv. p. 445), and admired it; moreover, I found myself in agreement with him. But it seems to me strange that Prof. Greenhill should approve of it. For Mr. Slate takes as his gravitational unit of force "*the weight of one pound under circumstances specified* . . . (*locality, vacuum*)." Surely this implies that he agrees with the theorists (Prof. Greenhill's foes) when they say that "the weight of a given body depends on the local value of g." Prof. Greenhill, on the contrary, speaking of *goods*, says that "*the weight cannot be said to vary with the local value of* g" (Nature, vol. xliv. p. 493), I would ask him, then—

(1) What name does he give to the earth's pull on a given body? Or, what is it that a spring balance measures when the said body is hung from it? He cannot say "its weight"; for the pull referred to varies with g, while Prof. Greenhill's "weight" does not. I conclude that he has no special name for it. The theorists have; and they thereby gain in brevity without losing by ambiguity, since they do not employ the word "weight" in any other sense in their text-books.

I would also repeat the still unanswered question—(2) How does Prof. Greenhill give the expression for hydrostatic pressure at a given depth in any locality, if he banishes "g"? (Nature, vol. xliv. p. 341). And does he conclude that Mr. Slate does not use "g" in hydrostatics?

Again . . . (3) Does Prof. Greenhill, in common with Mr. Slate and the theorists, use the word *mass* in speaking of the fundamental units; and, if so, in what sense?

In the science of dynamics we recognize two properties of matter: . . . (i.) its *inertia*; . . . (ii.) *the attraction between it and other matter*. The theorists use the word *mass* when they refer to quantity of matter as measured by its *inertia*; and they use the word *weight* when they refer to the *attraction* of a given body to the earth. For commercial purposes it is convenient to measure quantity of matter by balancing its weight against that of the standard lump of platinum, its multiples, and sub-multiples. Hence the every-day, slightly ambiguous, use of the word "weight" in matters in which we are not concerned with inertia. But in the science of dynamics, of which Newton's laws are the foundation, we are concerned *primarily* with *inertia*. The theorists, therefore, in their text-books, regard the well-known lump of platinum as *the standard pound, the British unit of mass*. They thus have the word "weight" free, and say (*e.g.*) that *the weight of the standard pound is measured by the resultant pressure that it exerts* (in vacuo) *on the bottom of the box in which it lies*. It requires more than general expressions of condemnation to show that any other system of nomenclature is clearer or less free from ambiguity, or that the equation $W = Mg$ has not as much meaning as any other dynamical equation. (I may refer back to my letter, Nature, vol. xliv. p. 493). W. Larden.

Devonport, September 26.

SOME NOTES ON THE FRANKFORT INTERNATIONAL ELECTRICAL EXHIBITION.[1]

IV.

Alternate Current Motors.

ALTERNATE current motors constitute one of the most striking features at the Frankfort Exhibition, and the commercial use of such motors will probably date from this year, so that the one great objection to the employment of alternating currents for the electric transmission and distribution of power will soon disappear.

It is well known that the direction of rotation of an ordinary series, or shunt, direct current motor is the same whichever way the direct current passes round the motor, in spite of a patent of Mr. Edison's to utilize the contrary fact on electric railways; hence it follows that if an alternate current be sent round such a motor it will start rotating and develop mechanical power. Only a comparatively small power and efficiency, however, will be obtained: first, because the large self-induction of the field magnet of the motor will seriously diminish the strength of the alternating current; secondly, because, in consequence of the rapid reversals of the magnetism, much power will be wasted in heating the iron core of the field magnet, even although this core be laminated like that of the armature.

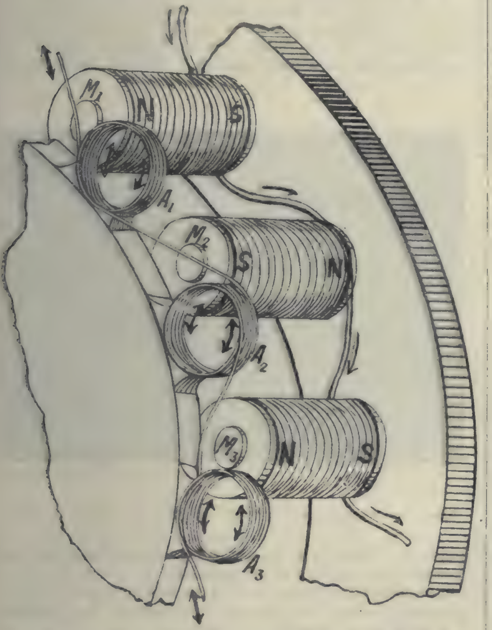

Fig 10.—Alternate current synchronizing motor. ← Direct current. ⟷ Alternating current.

If, on the other hand, a direct current be sent round the field magnet, M_1, M_2, M_3, of an *alternate* current machine, and an alternating current round the armature, A_1, A_2, A_3 (Fig. 10), the armature will not move, because at every two of the successive rapid reversals of the current the armature receives an impulse in opposite directions. To enable such a machine to work as a motor, it is necessary to first make the armature rapidly rotate by mechanical means at such a speed that any armature coil, A_2, moves forward by the distance between two of the poles M_2, M of the field magnet in half the periodic time of the alternation of the current. When this speed has been once attained, the machine will go on running as a powerful and efficient alternate current motor, at a perfectly definite speed, depending simply on the rate of alternation of the current, and independent within wide limits of the load put on the motor.

So that when the armature of the motor is once "in step" with that of the dynamo the two will continue "in step," whatever be the amount, within wide limits, of the power transmitted.

When a considerable amount of power has to be sent from a source to a distant town, and has there to be distributed for light or for driving machinery, it will certainly be best (as far as our present knowledge goes) to use alternating currents in the transmission of the power between the two distant places, because with alternating currents the pressure can so easily be transformed up at the source, and transformed down again at the other end of the line.

But in the distribution of the received power direct currents are the more convenient, since they can be utilized for light, for electroplating and electrotyping, as well as for small and large direct current electromotors, both of which have already reached a considerable degree of perfection, and are of course self-starting. Hence it is probable that there will be employed a synchronizing alternate current motor, coupled mechanically to a direct current dynamo, the latter being used to supply current to the town and excite the field magnets of the motor. Such combinations, seen in Fig. 11, are exhibited by Messrs. Siemens and Halske in the Frankfort Exhibition, the alternate current motor being to the left and the direct current dynamo to the right in the figure.

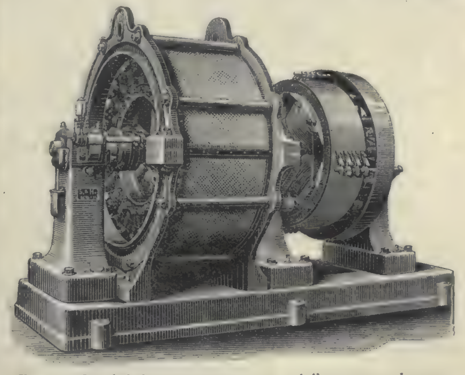

Fig. 11.—Coupled alternate current motor and direct current dynamo.

In the particular form of direct current dynamo shown in Fig. 11, and which represents a type much used now on the Continent, the field magnets are inside the rotating armature, and the wires on the outside of the Gramme ring itself are bare, and act as the commutator.

The impossibility of starting the simple synchronizing motor with an alternating current will be of little consequence when a large amount of power has to be transmitted, seeing that in the receiving station there will be several sets of geared alternate current motors and direct current dynamos, some of which will be always running day and night. Hence, to start any alternate current motor, all that need be done will be to send round the direct current dynamo, attached to the motor to be started, a portion of the direct current that is being produced by one of the running dynamos. This will cause the stationary direct current dynamo to start running as a motor, and when the right speed has been attained—that is, when the motor is in step with the distant alternate current dynamo—the alternate current can be switched on to the alternate current motor.

---

[1] Continued from p. 546.

Actual plans are being seriously got out at the present time, for using this exact method to transmit 5000 horse-power over forty miles in Tasmania, the received power being transformed by ten such combinations as are seen in Fig. 11, each of 500 horse-power.

This subdivision of the machinery at the receiving end, if accompanied by a similar subdivision of the generating plant at the sending end of the line, will have another most important advantage, viz. that a breakdown of a dynamo or of a motor will not cause a stoppage in the supply of power. A factory is, no doubt, worked at present with a single large engine; the propulsion of a steamer depends on the turning of a single powerful screw; but neither the unexpected stoppage of the factory engine for say half-an-hour once every two or three months, nor the delay of an Atlantic liner in mid-ocean for the same time once in every half-dozen voyages, would necessarily mean ruin. Were, however, the 10,000 horse-power dynamo at Deptford to be ever finished and worked at its full output, it would be necessary, in order to avoid a temporary hitch leading to the turning off the current from many thousands of glow lamps, and the plunging of a neighbourhood into darkness, to always have dynamos of a capacity of 10,000 horse-power kept idle in reserve.

Experience has shown that the size of each dynamo in a central station should be something like one-tenth of the maximum output, and that it is sufficient to keep one, or at the most two such dynamos, as a reserve, to prevent temporary breakdowns interfering with the steady supply of current. Until, then, a single central station is lighting some 500,000 glow lamps—or more than ten times the total number at present attached to the mains of the London Electric Supply Corporation—no one but the Brunel of electricity would have had the courage to embark on a 10,000 horse-power machine.

At any rate, when during the next year or two it is required to transmit a large amount of power over a considerable distance, it is probable that several alternate current synchronizing motors, each coupled to a direct current dynamo, will be employed at the receiving end of the line.

In cases, however, where there already exists an extended system of distributing alternate currents for electric light, the introduction of motors into small workshops and private houses will hardly be possible, unless the motors can be made self-starting. Mr. Zipernowski's motors, employed for driving the tools in a carpenter's shop at the Frankfort Exhibition, have been made self-starting, and also fairly efficient, by adopting a compromise between the simple direct current motor, which is self-starting but inefficient when used with alternating currents, and the alternate current synchronizing motor, which is efficient but not self-starting.

The device employed by Mr. Zipernowski, and which is based on a communication made by Prof. G. Forbes to the Royal Society of Edinburgh some eight years ago, is as follows:—Send the alternating current round the field magnet as well as round the armature of an alternate current motor (Fig. 10), and attach a commutator to the armature so as to reverse the current flowing round the field magnet every time the armature coils A_1, A_2, A_3 pass the field magnet coils M_1, M_2, M_3. On sending the alternate current round such a motor, the motor will start, but since at first the rapidity of alternation of the current will be far greater than the rapidity of commutation there will be much sparking at the commutator and waste of power. As, however, the armature turns more and more quickly, the commutation will be effected more and more rapidly, until at last the armature will attain such a speed that every time the current is reversed by the distant dynamo the portion of the current flowing round the field magnet of the motor will be commutated by the rapidly rotating armature. Hence the current flowing round this field magnet will now be always in the same direction. But as it will not be always of the same strength there will be more waste of power than with a simple synchronizing motor.

Such an arrangement as that adopted by Mr. Zipernowski, then, furnishes a motor which, although not as efficient and powerful for its weight as the synchronizing motor previously described, has the advantage of synchronizing fairly well, of being self-starting, and of giving far better results than a direct current motor with laminated field magnets used with alternating currents.

It is possible, however, as proved by Prof. Ferraris in 1885, to design an alternate current motor on totally different principles, and to construct a machine which will work not merely without a commutator, but without even any sort of rubbing contact. So that, in fact, the ends of all the wires on a Ferraris motor may be permanently soldered, and the motor left in the hands of a person who knows how to oil a machine but who is quite ignorant of the trimming and adjustment of the brushes of an ordinary direct current motor.

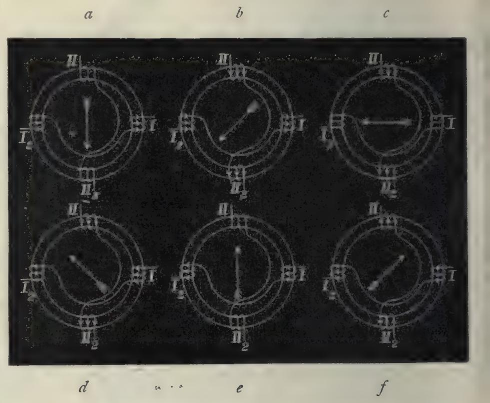

FIG. 12.—Rotating magnetic field produced by two alternating currents.

Round an iron ring are wound four coils, as seen in Fig. 12, and through the two distinct circuits are sent two harmonic alternating currents having the same periodic time and maximum amptitude, but differing by 90° in phase. The ring will therefore receive two magnetizations along two fixed diameters at right angles to one another, the two magnetizations alternating approximately according to the sine function of the time, and differing by 90° in phase. And the composition of these two magnetizations will give a "*rotating magnetic field*," which will make one complete rotation in the periodic time of alternation of the current.

Six values of these two currents are indicated in Fig. 12, the currents in *a*, *c*, and *e*, being of their maximum value in coils I, I_2, and nought in coils II, II_2; while in *b*, *d*, and *f*, the currents in the four coils are equal, being each $\frac{1}{\sqrt{2}}$ of the maximum value. The arrow indicates the position which in each case would be taken up by a suspended compass needle, the point of the arrow indicating the north-seeking pole of the compass needle.

If in place of the suspended compass needle there be a piece of copper, currents will be induced in this copper by the rotating magnetic field, tending to make the cylinder follow the field. Hence, if the copper take the form of a cylinder, with its axis coinciding with the axis of the ring, and supported so that it can rotate about this axis, the cylinder will run after the rotating field until it catches it up, when the two will move nearly synchronously together. On applying a resistance to the rotation of this cylinder—that is, on making the motor do work—the speed of the cylinder will be checked, but a small diminution of speed will cause large currents to be induced in the copper, and a pulling force to be exerted between the rotating field and the lagging cylinder, tending to drag the cylinder round. Hence this arrangement of Prof. Ferraris produces not merely a self-starting alternate current motor, but one which runs almost synchronously with the dynamo for wide variations in the load, and which has neither commutator, rubbing contacts, brushes, nor the possibility of sparking.

Within the past few weeks we have learnt that the idea of obtaining a rotating magnetic field was mentioned by M. Marcel Deprez, in a French patent dated May 1883. In that patent, when speaking of the magnetic field produced by the current flowing round a Gramme ring, he says: "*Cette rotation du champ magnétique peut être obtenue sans faire mouvoir aucune pièce; pour cela on fera naitre le champ à l'aide de deux courants dont les points d'entrée sont sur deux diamètres perpendiculaires; l'aimentation de ce champ sera alors une résultante dont la position dépend des intensités relatives des deux courants, ainsi que cela a été décrit ci-dessus pour le comparateur des courants; il suffit de faire varier le rapport de ces intensités pour faire tourner cette résultante, et avec elle le champ magnétique.*"

It does not, however, appear to have occurred to M. Deprez that this rotation of a magnetic field might be employed to induce currents, and thus give motion to a piece of metal placed inside the Gramme ring; nor does he say anything about two harmonic alternate currents differing by 90° in phase producing the exact variation of current required. Although, then, what may be called the geometrical idea of producing a rotating magnetic field was certainly clearly described by M. Deprez, the credit of rediscovering this principle, and, what is far more important, of applying it in the design of the two-phase alternate current motor, is due to Prof. Ferraris.

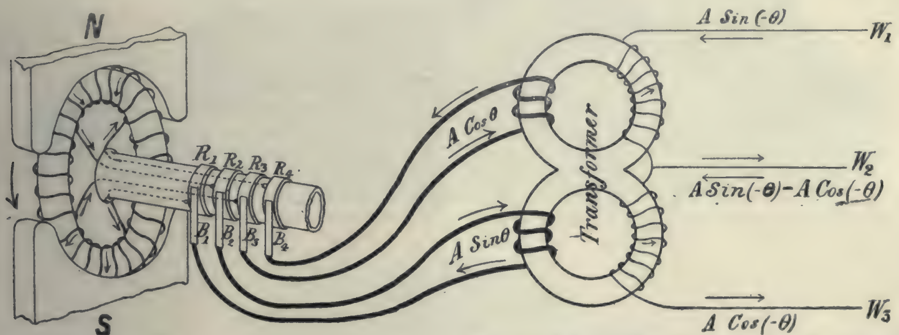

FIG. 13.—Schuckert two-phase alternate current generator and transformer. The arrows indicate the actual direction of the currents for the position of the armature shown.

To increase the strength of the rotating magnetic field, the copper cylinder originally used by Prof. Ferraris was next made hollow, and the interior filled with soft iron, the iron being laminated in planes at right angles to the axis, to prevent currents being induced in the iron; and to make the currents induced in the copper cylinder follow the most useful path the next step was to make a number of cuts through the hollow copper cylinder parallel to the axis of rotation. Practically, then, the rotating portion becomes a laminated cylinder of iron, on which is wound insulated wire parallel to the axis, as in a Siemens armature, but with this difference, that all the wires are electrically joined together at each end of the cylinder.

A two-phase alternate current motor was constructed and used by Prof. Ferraris in his laboratory at Turin in 1885. But not appreciating the practical importance of his own invention, and thinking that no motor requiring more than two wires could interest anyone but the natural philosopher, Prof. Ferraris occupied himself with attempts to utilize the rotatory magnetic field in measuring the resistance of conductors and with mathematical investigations on alternate currents. It was not, therefore, until the spring of 1888 that the results of his researches were published; when, a few months later, commercial motors based on exactly the same principles were brought out with considerable *éclat* by Mr. Tesla, of Pittsburg, who had been working independently in the same direction.

To produce two alternate currents, differing by 90° in phase, the following device (Fig. 13) may be adopted, and is the one employed by Messrs. Schuckert in transmitting power at 2000 volts from the Palm Garden at Frankfort to the Exhibition, and by Messrs. Siemens and Halske for experiments on rotatory field alternate current motors in the Exhibition; the latter firm, however, not employing the special form of transformer shown symbolically in Fig. 13. In addition to the armature of a Gramme dynamo being joined up in the well-known way with the ordinary direct current commutator (this commutator and brushes rubbing on it not being shown in Fig. 13), four points at equal distances on the armature are permanently connected with four metal rings, R_1, R_2, R_3, and R_4, which rotate with the armature. Then it is easy to prove that while the machine is producing a direct current, used for exciting the field magnets as well as for any other purpose desired, the current passing through the wires attached to the brushes B_1, B_2, and the current passing through the wires attached to the brushes B_3, B_4, each alternate very nearly as the sine function of the time, the one reaching its maximum value when the other is nought.

The actual machine employed for this purpose by Messrs. Schuckert is the multipolar dynamo shown in Fig. 14, the direct current commutator and brushes, as well as the four rings and brushes for the two alternating currents, being here seen. If rotated mechanically, it will produce a direct current, as well as two alternating currents differing by 90° in phase; if supplied with a direct current, it will rotate as a motor generating the two alternate currents, and also doing mechanical work if required; lastly, if supplied with the two alternate currents, it will work as a two-phase alternate current motor generating a direct current, as well as doing mechanical work.

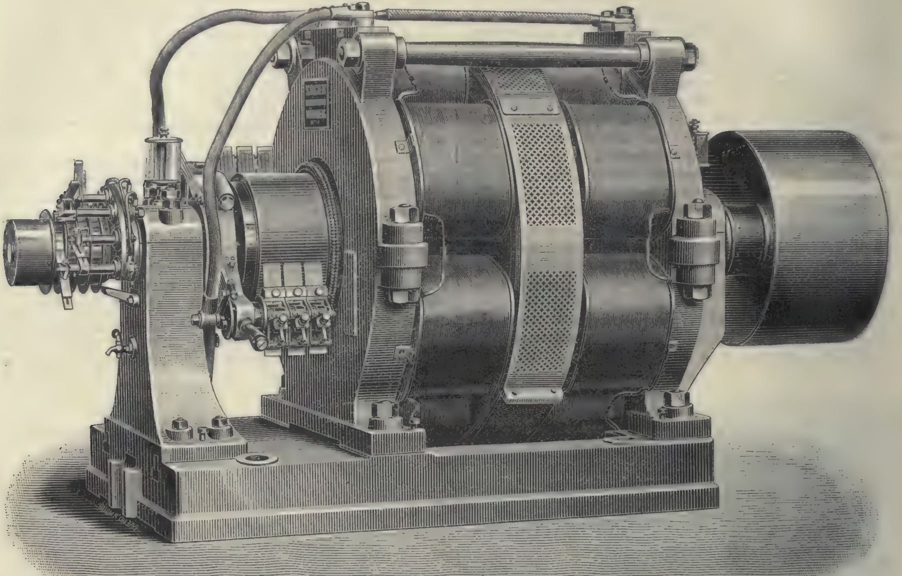

Fig. 14.—Schuckert's two-plane alternate current generator, or motor, or apparatus for transforming two alternate currents into a direct current.

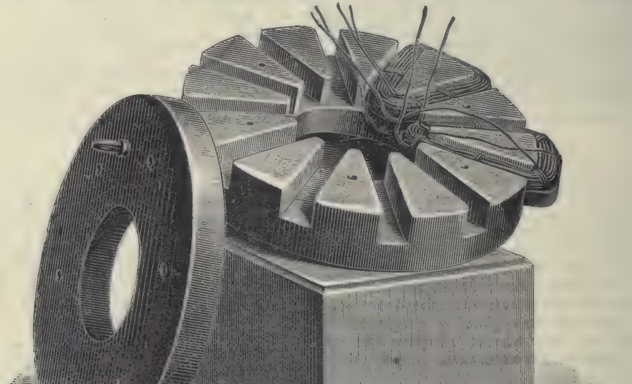

Fig. 15.—Schuckert two-phase alternate current transformer (method of construction).

When transmitting power to a distance, the two-phase alternate potential differences are transformed up from about 100 to 2000 volts; and to enable the transmission to be effected with three wires instead of four, Messrs. Schuckert arrange the transformer at each end of the line as shown symbolically in Fig. 13. Hence, if the currents produced by the dynamo be represented by A sin θ and A cos θ, the currents in the main wires, W_3, W_1, and W_2, will be represented by A cos $(-\theta)$, A sin $(-\theta)$, and A $\{\sin(-\theta) + \cos(-\theta)\}$ respectively.

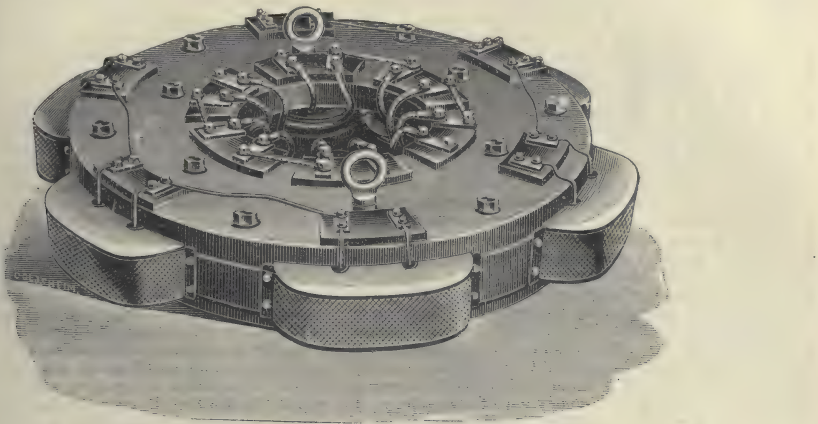

Fig. 16.—Schuckert two-phase alternate current transformer (completed).

The actual method employed by Messrs. Schuckert for winding this special transformer, as well as its appearance when completed, are seen from Figs. 15 and 16. This transformer, then, instead of consisting of merely a double ring of laminated iron as indicated in the symbolical diagram, Fig. 13, may be regarded as being composed of a connected series of laminated iron rings, each of a wedge-shaped cross-section.

(*To be continued.*)

THE OXFORD UNIVERSITY MUSEUM.[1]

THE following memorandum is based, not only upon observations made during a recent visit to Oxford, but also upon a fairly intimate knowledge of the origin and progress of the different departments of the Museum, acquired at various intervals of time extending over more than thirty years.

In entering upon the consideration of the subject which you have referred to me, it will first be necessary to define the purposes for which the Museum is maintained. These I take to be somewhat manifold, but they may be classed as follows:—

A. The first and main purpose is undoubtedly to assist in the educational work of the University, by illustrating the teaching of the professors and lecturers.

Besides this, however, it subserves, to a greater or less degree, other and what may be considered, as compared with the first, secondary, but nevertheless important functions. These are—

B. The exhibition of a collection, arranged in a systematic, orderly, and attractive manner, open to the inspection, under proper regulations, of all members of the University, and also of residents in and visitors to the town, which shall tend to awaken and keep up an interest in various subjects of which most educated persons, besides those actually engaged at the moment in obtaining instruction, desire to possess some knowledge. Such a collection is a most legitimate adjunct to the University as a place of general culture.

C. Certain collections have already, and possibly will in future, become added to the general Museum, the aim and scope of which reach beyond either of the above, being of value, not to the ordinary student, not to the man or woman of average general culture, but only to the advanced student who wishes to enter seriously into the pursuit of some special branch of knowledge. Such is the Hope Collection of Insects, and to a certain extent the Pitt-Rivers Ethnographical Collection.

It is a grave question how far such collections should be maintained at the cost of the University. On the one hand, they must be a cause of expense, without which no collection of any value can be maintained; and the larger and better ordered they are, the greater must be the cost of maintaining them. Unless properly cared for, not only as regards actual preservation of the objects contained in them, but also as regards the continual re-arrangements and augmentations necessitated by the advance of science, they will become comparatively valueless in the course of time. If the care of many such collections were undertaken unaccompanied by special endowments for their maintenance, the burden would become such as only a national institution could afford.

On the other hand, looking at the University, not merely as a place for the education of youth, but also as a centre of culture for the whole country, the possession of some such collections is of great importance. As they contain in them objects which can be found nowhere else, they attract men of learning and science, not only from other parts of the country, but also from distant places, to visit the University, or even to become permanent residents. The value of collections of rare books, even upon subjects interesting to scholars whose numbers are very limited, have long been recognized. From the same point of view, special collections of rare specimens of natural history or works of art may take their place in the general scheme of a University Museum, but the care of such collections should not be undertaken without full consideration as to whether the means will be forthcoming to maintain them in a state of efficiency.

---

[1] Prof. Flower's Report to the Committee on Collections appointed by the Delegates of the University Museum, Oxford, dated March 14, 1891.

I have alluded to the Pitt-Rivers Collection as coming partly under this head, but, admirably and instructively displayed as it now is, it may also be considered as belonging to my second category; and the numerous human interests awakened by a study of its contents, and the many branches of culture it comes in contact with, make it an adjunct to the Museum, of the great importance of which no one should entertain a doubt. I should be glad to remark, in passing, that the building in which it is housed appears to me the most successful, as regards economy of space, capacity for orderly arrangement, and good lighting, of any with which I am acquainted.

The next point for consideration is the nature and extent of the subjects to be illustrated in the Museum (excluding the special Pitt-Rivers Collection just referred to). These seem already to have been determined as including physiology, human anatomy, comparative anatomy, animal morphology, zoology, pathological anatomy, palæontology, geology, and mineralogy; therefore the whole of animal biology (botany being provided for elsewhere), with the addition of geology and mineralogy. The teaching of these subjects is divided between the Regius Professor of Medicine, the Waynflete Professor of Physiology, the Linacre Professor of Human and Comparative Anatomy, the Lecturer in Human Anatomy, the Hope Professor of Zoology, the Professors of Geology and of Mineralogy. It must be recognized by everyone that the boundaries of these subjects are most difficult to define, and must be constantly shifting with the advance of knowledge. For instance, comparative anatomy and palæontology may both be included under the broad general heading of zoology, which without the aid of both can be but imperfectly understood. Whatever dividing lines are drawn between different sections of the collection, identical specimens are often required to illustrate more than one subject. The remains of extinct animals are required to complete the story of their living representatives; they are also required to illustrate the ancient history of the earth, and to define the progress of geological time and the order and succession of strata. The relation between the collections used to illustrate the teaching of the Waynflete, the Linacre, and the Hope Professors, must also be more or less arbitrary and artificial. In all these matters mutual convenience must be studied, and the specimens which lie on the borderland of two subjects should be made in some way available for the teaching of both, otherwise a great duplication will be necessary.

With regard to general administration, it appears to me desirable that there should be a governing body for the whole Museum, comparable to the standing committee of the Trustees of the British Museum, or the Museum Committee of the Royal College of Surgeons, or the Museums Syndicate of the University of Cambridge. The Delegates constitute such a body at Oxford, but possibly their constitution or powers might be modified and more clearly defined than they seem to be at present.

This body should be composed of members of the University specially selected for fitness for the office; seven or nine would probably be the most convenient number, so that representatives may be found upon it of various branches of science included in the Museum, and also some members of general business or administrative capacity. They should meet at occasional and stated intervals, and should determine general questions affecting the Museum as a whole, the relations of its component elements one to another, the allotment of space and the apportionment of the grants for the service of each department, the general control of expenditure, and also the care of the building, furniture, &c. It is not advisable that they should interfere with the details of the arrangement of each department as long as these appear to be satisfactorily carried out. The Keeper of the Museum should be the active executive officer of this governing body, carrying out their views in the intervals of the meetings, and bringing before their notice any subjects which seem to require their consideration.

Each professor, as the representative of the most advanced state of knowledge of his subject, should be the responsible curator of the specimens belonging to his department, having such assistance provided him as may be needful. He should be called upon to present to the governing body an annual report of the condition of the collections under his care, and of the accessions which have been made to it during the year.

The actual specimens in the various collections will naturally arrange themselves, both as regards the purpose for which they are kept, and their mode of conservation, under three distinct classes.

1. A working set, mostly of common objects, which, if damaged, can be readily replaced, and which can be put at the disposition of the ordinary student to examine and handle. Such collections are absolutely essential to practical teaching, but they should form no part of the permanent Museum of the University, and should be kept in the rooms specially devoted to study.

2. The permanent exhibited series displayed in the grand court and corridors of the Museum, the use of which, in addition to teaching students, is referred to under the heading B, near the beginning of this report. Great care is required in selecting and arranging these, as well as in their preservation and display. Every specimen exhibited should have a definite object, and should be so placed that it can be thoroughly well seen. As a general rule they should be so arranged as to show what they are intended to teach without moving them from their places, and if this must be done under proper restrictions, all due precautions should be used that they do not become damaged or destroyed. Although for the purposes of custody, arrangement, and nomenclature, these must be under the care of a particular professor, they are in a certain sense the common property of all who have a right of access to the Museum. This is another reason for not removing them from their places (apart from the injury that might thereby accrue to them) without definite cause, as they should be always available for study, the professors and demonstrators rather bringing their classes to them than removing them to the class-rooms.

3. The collections kept for advanced researches. Although these are not exhibited in the ordinary sense of the word, they should, if retained at all, be kept in a situation and under conditions which make them readily accessible to all who can profit by their examination under suitable regulations. Their preservation is of the utmost importance in the progress of science, as among them are often to be found zoological "types," or the individual specimens upon which the name of the species was instituted, and which must be referred to by zoologists for all future time in cases of difficulty in determining that name. To permit the loss or deterioration of a "type" specimen is a serious offence in the eyes of the zoologist. The Hope Collection abounds in such types.

Nothing more need be said at present about the first and third of these sections of the Museum, but the second, the exhibited series occupying the body of the great hall, requires consideration in a little more detail.

It is divided at present into—

(1) Mineralogy. Of the value and arrangement of this section I am not competent to speak.

(2) Geology. This collection is mainly palæontological, and the arrangement appears to be partly stratigraphical and partly zoological. In many groups the collection is rich, but taking it altogether there appears to be a number of unnecessary duplicates, and much rearrangement is

required to bring it into good exhibition and teaching order. I would suggest that in a collection illustrating *geology* (and not the zoology of extinct animals, so often in museums confounded with that science) the stratigraphical arrangement should be followed as strictly as possible, and also that there should be a good series illustrating dynamical geology, or the processes by which the materials forming the earth's crust have been fashioned and arranged as we now see them.

(3) Animal Biology. This section occupies about two-thirds of the floor space of the Museum, and is at present broken up into various small series involving much repetition and duplication, and also difficulty of finding any particular object or illustration required.

In the middle of the hall is a series of specimens merely showing the external appearance of certain groups of animals, stuffed vertebrates and the shells of mollusks, and stony skeletons of corals, &c. If this collection were incorporated in the general series of animal biology, not only would much duplication be avoided, but a more instructive and scientific exhibition would be provided. Many of the present specimens of this series, especially the mounted mammals and birds, are in such bad condition that they have no educational value—they only mislead instead of teaching; but before destroying them they should all be submitted to the examination of some expert in the group to which they belong, as there may be interesting or rare specimens among them, though their value is scarcely to be recognized by the ordinary observer in their present condition.

The imperfection of any zoological series that does not illustrate extinct as well as recent forms is continually becoming more apparent as science advances; some attempts have already been made to remedy this defect in the zoological series, but a considerable transfer of specimens to it from the department of geology will result in advantage to both.

By a rearrangement of the biological series, with incorporation of the so-called zoological specimens (excluding the Hope Collection, which I presume is always to be kept apart) much economy of space could be effected, and some of the confusion which now appears to exist in this department of the Museum in consequence of the numerous apparently independent series of specimens will be obviated.

The great question of the primary arrangement of the biological collection, whether on the physiological or Hunterian system, or upon a system based upon zoological classification, will have to be carefully considered. Much is to be said for either, but whichever is adopted should follow the method of teaching of the professor and his assistants. The point to be aimed at is that every specimen should be readily found, and be in juxtaposition with other specimens which are related to it, and which should be studied in conjunction with it. As the classification of animals, except as regards the greater divisions, is still a matter of much uncertainty, and continually changing according to the advance of knowledge, or the opinions of individual zoologists, it is not a satisfactory basis for the arrangement of a collection intended to illustrate principles rather than details. On the other hand, the Hunterian system often brings into juxtaposition specimens related only by some remote analogy of function, and having no real correspondence or homology. Probably a zoological arrangement for the main divisions, and one based upon a comparison of organs or systems for the secondary divisions, will, on the whole, be found most convenient.

I am hardly in a position to say how far the Professor of Physiology requires a special collection to illustrate his teaching. Probably the general biological series will supply all that is necessary to refer to in illustration of his lectures, especially as the tendency of modern physiology seems to be to separate itself from morphology, and confine itself more to biological chemistry and dynamics.

Another question which has been raised is, whether human anatomy, as distinguished from general biology, requires a separate section of the Museum, and how the great and important collection of crania of the races of men, which under Prof. Rolleston became one of the special features of the Museum, should be treated and utilized for instruction. These are questions that time will probably solve. Much depends upon the view taken of the duties of the Lecturer on Human Anatomy, whether he should teach upon a broad and philosophical basis, or whether he should aim mainly at enabling his pupils to pass the standard now required by the examining bodies. But this trenches upon the larger and more complex subject of what should be the aim of the University in keeping up a Medical School.

The Pathological Collection will, of course, remain as at present under the care of the Professor of Medicine.

In looking round the Museum at the present time, one of its greatest wants appears to me to be proper labelling. The different sections of the Museum should be distinctly marked off from each other. Every case should have a conspicuous label on the top of it, indicating the nature of its contents. Every specimen should have one indicating why it is there and what it teaches. This will involve a large amount of labour and expense in printing, but it is absolutely necessary, if the collections are to fulfil the purpose for which they are formed. It is a mistake to spend much time, labour, and cost in obtaining, preparing, and preserving a specimen, and then to stop short of the one thing needed to make it of use. Better have fewer specimens in a complete state. A printing press might be established in the building and kept constantly at work, but as it would be difficult to apportion the claims upon its services of the different curators, it might be better to make an arrangement with the University Press by which labels (of a uniform character) for the whole Museum would be printed at a fixed charge, and paid for out of the funds of the department requiring them. As in a large number of cases only a single copy of a label is required, it is possible that some system of type-writing might be more economical, and nearly, if not quite, as effectual.

Of the importance of complete catalogues of every department of the Museum, it would seem almost superfluous to speak, were it not obvious that much is needed in this respect.

Lastly, it appears to me that, although more work-rooms and class-rooms may be necessary for the growing needs of the scientific departments of the University, there is ample space in the present building for some time to come for the exhibited portion of the Museum. The collections are rich, contain many instructive and valuable objects, and do great credit to the zeal and energy of those by whom they have been brought together. What is really required now is, not so much that they should be increased, as that they should be better arranged, better cared for, and that all inferior and defective specimens should be gradually replaced by better ones. Oxford has done very much in past times to initiate and keep up a high standard of museum work, but it must not be overlooked that great advances are being made in this respect, not only in this country but all over the Continent, and the standard is being continually raised. All such work is both laborious and costly, but when done the result is fully commensurate to the labour and expense bestowed upon it. An ill-arranged museum has been well compared to the letters of the alphabet tossed about indiscriminately, meaning nothing; a well-arranged one to the same letters placed in such orderly sequence as to produce words of counsel and instruction.

FURTHER RESEARCHES UPON THE ELEMENT FLUORINE.

SINCE the publication by M. Moissan of his celebrated paper in the *Annales de Chimie et de Physique* for December 1887, describing the manner in which he had succeeded in isolating this remarkable gaseous element, a considerable amount of additional information has been acquired concerning the chemical behaviour of fluorine, and important additions and improvements have been introduced in the apparatus employed for preparing and experimenting with the gas. M. Moissan now gathers together the results of these subsequent researches—some of which have been published by him from time to time as contributions to various French scientific journals, while others have not hitherto been made known—and publishes them in a long but most interesting paper in the October number of the *Annales de Chimie et de Physique*. Inasmuch as the experiments described are of so extraordinary a nature, owing to the intense chemical activity of fluorine, and are so important as filling a long existing vacancy in our chemical literature, readers of NATURE will doubtless be interested in a brief account of them.

IMPROVED APPARATUS FOR PREPARING FLUORINE.

In his paper of 1887, the main outlines of which were given in NATURE at the time (1887, vol. xxxvii. p. 179), M. Moissan showed that pure hydrofluoric acid readily dissolves the double fluoride of potassium and hydrogen, and that the liquid thus obtained is a good conductor of electricity, rendering electrolysis possible. It will be remembered that, by passing a strong current of electricity through this liquid contained in a platinum apparatus, free gaseous fluorine was obtained at the positive pole and hydrogen at the negative pole. The amount of hydrofluoric acid employed in these earlier experiments was about fifteen grams, about six grams of hydrogen potassium fluoride, $HF.KF$, being added in order to render it a conductor. Since the publication of that memoir a much larger apparatus has been constructed, in order to obtain the gas in greater quantity for the study of its reactions, and important additions have been made, by means of which the fluorine is delivered in a pure state, free from admixed vapour of the very volatile hydrofluoric acid. As much as a hundred cubic centimetres of hydrofluoric acid, together with twenty grams of the dissolved double fluoride, are submitted to electrolysis in this new apparatus, and upwards of four litres of pure fluorine is delivered by it per hour.

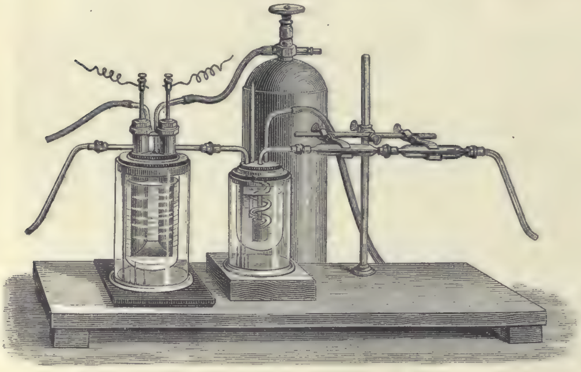

Fig. 1.

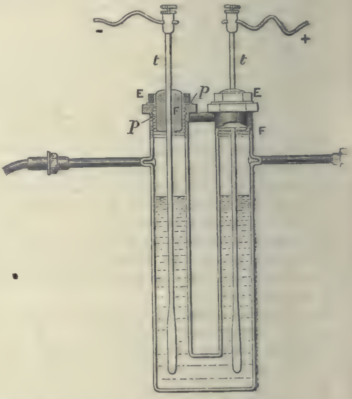

Fig. 2.

This improved form of the apparatus is shown in the accompanying figure (Fig. 1), which is reproduced from the memoir of M. Moissan. It consists essentially of two parts—the electrolysis apparatus and the purifying vessels. The electrolysis apparatus, a sectional view of which is given in Fig. 2, is similar in form to that described in the paper of 1887, but much larger. The U-tube of platinum has a capacity of 160 c.c. It is fitted with two lateral delivery tubes of platinum, as in the earlier form, and with stoppers of fluor-spar, F, inserted in cylinders of platinum, *p*, carrying screw threads, which engage with similar threads upon the interior surfaces of the limbs of the U-tube. A key of brass, E, serves to screw or unscrew the stoppers, and between the flange of each stopper and the top of each branch of the U-tube a ring of lead is compressed, by which means hermetic closing is effected. These fluor-spar stoppers, which are covered with a coating of gum-lac during the electrolysis, carry the electrode rods, *t*, which are thus perfectly insulated. M. Moissan now employs electrodes of pure platinum instead of irido-platinum, and the interior end of each is thickened into a club shape in order the longer to withstand corrosion. The apparatus is immersed during the electrolysis in a bath of liquid methyl chloride, maintained in tranquil ebullition at -23°. In order to preserve the methyl chloride as long as possible, the cylinder containing it is placed in an outer glass cylinder containing fragments of calcium chloride; by this means it is surrounded with a layer of dry air, a bad conductor of heat.

The purifying vessels are three in number. The first consists of a platinum spiral worm-tube, of about 40 c.c. capacity, immersed also in a bath of liquid methyl chloride, maintained at as low a temperature as possible, about -50°. As hydrofluoric acid boils at $19^{\circ}\cdot5$ (Moissan), almost the whole of the vapour of this substance which is carried away in the stream of issuing fluorine is condensed and retained at the bottom of the worm. To remove the last traces of hydrofluoric acid, advantage is taken of the fact that fused sodium fluoride combines with the free acid with great energy to form the double fluoride $HF.NaF$. Sodium fluoride also possesses the advantage of not attracting moisture. After traversing the worm condenser, therefore, the fluorine is caused to pass through two platinum tubes filled with fragments of fused sodium fluoride, from which it issues in an almost perfect state of purity. The junctions between the various parts of the apparatus are effected by means of screw joints, between the nuts and flanges of which collars of lead are compressed. During the electrolysis these leaden collars become, where exposed to the gaseous fluorine, rapidly converted into lead fluoride, which, being greater in bulk, causes the joints to become hermetically sealed. In order to effect the electrolysis, 26 to 28 Bunsen elements are employed, arranged in series. An ampere-meter and a commutator are introduced between the battery and the electrolysis apparatus; the former affording an excellent indication of the progress of the electrolysis.

As the U-tube contains far more hydrofluoric acid than can be used in one day, each lateral delivery-tube is fitted with a metallic screw stopper, so that the experiments may be discontinued at any time, and the apparatus closed. The whole electrolysis vessel is then placed under a glass bell-jar containing dry air, and kept in a refrigerator until again required for use. In this way it may be preserved full of acid for several weeks, ready at any time for the preparation of the gas. Considerable care requires to be exercised not to admit the vapour of methyl chloride into the U-tube, as otherwise violent detonations are liable to occur. When the liquid methyl chloride is being introduced into the cylinder, the whole apparatus becomes surrounded with an atmosphere of its vapour, and as the platinum U-tube is at the same instant suddenly cooled, the vapour is liable to enter by the abducting tubes. Consequently, as soon as the current is allowed to pass and fluorine is liberated within the U-tube, an explosion occurs. Fluorine instantly decomposes methyl chloride, with production of flame and formation of fluorides of hydrogen and carbon, liberation of chlorine, and occasionally deposition of carbon. In order to avoid this unpleasant occurrence, when the methyl chloride is being introduced the ends of the lateral delivery-tubes are attached to long lengths of caoutchouc tubing, supplied at their ends with calcium chloride drying tubes, so as to convey dry air from outside the atmosphere of methyl chloride vapour. If great care is taken to obtain the minimum temperature, this difficulty may be even more simply overcome by employing a mixture of well-pounded ice and salt instead of methyl chloride; but there is the counterbalancing disadvantage to be considered, that such a cooling bath requires much more frequent renewal.

CHEMICAL REACTIONS OCCURRING DURING THE ELECTROLYSIS.

In the paper of 1887, M. Moissan adopted the view that the first action of the electric current was to effect the decomposition of the potassium fluoride contained in solution in the hydrofluoric acid, fluorine being liberated at the positive pole, and potassium at the negative terminal. This liberated potassium would at once regenerate potassium fluoride in presence of hydrofluoric acid, and liberate its equivalent of hydrogen:

$$\mathrm{KF} = \mathrm{K} + \mathrm{F}.$$
$$\mathrm{K} + \mathrm{HF} = \mathrm{KF} + \mathrm{H}.$$

But when the progress of the electrolysis is carefully followed, by consulting the indications of the amperemeter placed in circuit, it is found to be by no means as regular as the preceding formulæ would indicate. With the new apparatus, the decomposition is quite irregular at first, and does not attain regularity until it has been proceeding for upwards of two hours. Upon stopping the current and unmounting the apparatus, the platinum rod upon which the fluorine was liberated is found to be largely corroded, and at the bottom of the U-tube a quantity of a black, finely-divided substance is observed. This black substance, which was taken at first to be metallic platinum, is a complex compound, containing one equivalent of potassium to one equivalent of platinum, together with a considerable proportion of fluorine. Moreover, the hydrofluoric acid is found to contain a small quantity of platinum fluoride in solution. The electrolytic reaction is probably therefore much more complicated than was at first considered to be the case. The mixture of acid and alkaline fluoride furnishes fluorine at the positive terminal rod, but this intensely active gas, in its nascent state, attacks the platinum and produces platinum tetrafluoride, $\mathrm{PtF_4}$; this probably unites with the potassium fluoride to form a double salt, possibly $\mathrm{2KF.PtF_4}$, analogous to the well-known platinochloride $\mathrm{2KCl.PtCl_4}$; and it is only when the liquid contains this double salt that the electrolysis proceeds in a regular manner, yielding free fluorine at the positive pole, and hydrogen and the complex black compound at the negative pole.

PHYSICAL PROPERTIES OF FLUORINE.

Fluorine possesses an odour which M. Moissan compares to a mixture of hypochlorous acid and nitrogen peroxide, but this odour is usually masked by that of the ozone which it always produces in moist air, owing to its decomposition of the water vapour. It produces most serious irritation of the bronchial tubes and mucous membrane of the nasal cavities, the effects of which are persistent for quite a fortnight.

When examined in a thickness of one metre, it is seen to possess a greenish-yellow colour, but paler, and containing more of yellow, than that of chlorine. In such a layer, fluorine does not present any absorption-bands. Its spectrum exhibits thirteen bright lines in the red, between wave-lengths 744 and 623. Their positions and relative intensities are as follows:—

λ = 744	very feeble.	λ = 685·5	feeble.
740	,,	683·5	,,
734	,,	677	strong.
714	feeble.	640·5	,,
704	,,	634	,,
691	,,	623	,,
687·5	,,		

At a temperature of − 95° at ordinary atmospheric pressure, fluorine remains gaseous, no sign of liquefaction having been observed.

METHODS OF EXPERIMENTING WITH FLUORINE.

When it is desired to determine the action of fluorine upon a solid substance, the following method of procedure is adopted. A preliminary experiment is first made, in order to obtain some idea as to the degree of energy of the reaction, by bringing a little of the solid, placed upon the lid of a platinum crucible held in a pair of tongs, near the mouth of the delivery-tube of the preparation apparatus. If a gaseous or liquid product results, and it is desirable to collect it for examination, small fragments of the solid are placed in a platinum tube connected to the delivery-tube by flexible platinum tubing or by a screw joint, and the resulting gas may be collected over water or mercury, or the liquid condensed in a cooled cylinder of platinum. In this manner the action of fluorine upon sulphur and iodine has been studied. If the solid, phosphorus for instance, attacks platinum, or the temperature of the reaction is sufficiently high to determine the combination of platinum and fluorine (towards 500°), a tube of fluor-spar is substituted for the platinum tube. The fluor-spar tubes employed by M. Moissan for the study of the action of phosphorus were about twelve to fourteen centimetres long, and were terminated by platinum ends furnished with flanges and screw threads in order to be able to connect them with the preparation apparatus. If it is required to heat the fluor-spar tubes, they are surrounded by a closely wound copper spiral, which may be heated by a Bunsen flame.

In experimenting upon liquids, great care is necessary, as the reaction frequently occurs with explosive violence. A preliminary experiment is therefore always made, by allowing the fluorine delivery-tube to dip just beneath the surface of the liquid contained in a small glass cylinder. When the liquid contains water, or when hydrofluoric acid is a product of the reaction, cylinders of platinum or of fluor-spar are employed. If it is required to collect and examine the product, the liquid is placed along the bottom of a horizontal tube of platinum or fluor-spar, as in case of solids, connected directly with the preparation apparatus, and the product is collected over water or mercury if a gas, or in a cooled platinum receiver if a liquid.

During the examination of liquids a means has accidentally been discovered by which a glass tube may be filled with fluorine gas. A few liquids, one of which is carbon tetrachloride, react only very slowly with fluorine at the ordinary temperature. By filling a glass tube with such a liquid, and inverting it over a platinum capsule also containing the liquid, it is possible to displace the liquid by fluorine, which, as the walls are wet, does not attack the glass. Or the glass tube may be filled with the liquid, and then the latter poured out, leaving the walls wet; the tube may then be filled with fluorine gas, which, being slightly heavier than air, remains in the tube for some time. In one experiment, in which a glass test-tube had been filled with fluorine over carbon tetrachloride, it was attempted to transfer it to a graduated tube over mercury, but in inclining the test-tube for this purpose, the mercury suddenly came in contact with the fluorine, and absorbed it so instantaneously and with such a violent detonation that both the test-tube and the graduated tube were shattered into fragments. Indeed, owing to the powerful affinity of mercury for fluorine, it is a most dangerous experiment to transfer a tube containing fluorine gas, filled according to either the first or second method, to the mercury trough; the tube is always shattered if the mercury comes in contact with the gas, and generally with a loud detonation. Fluorine may, however, be preserved for some time in tubes over mercury, provided a few drops of the non reacting liquid are kept above the mercury meniscus.

For studying the action of fluorine on gases, a special piece of apparatus, shown in Fig. 3, has been constructed.

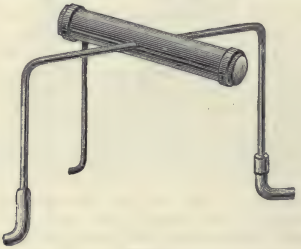

Fig. 3.

It is composed of a tube of platinum, fifteen centimetres long, closed by two plates of clear, transparent, and colourless fluor-spar, and carrying three lateral narrower tubes also of platinum. Two of these tubes face each other in the centre of the apparatus, and serve one for the conveyance of the fluorine and the other of the gas to be experimented upon. The third, which is of somewhat greater diameter than the other two, serves as exit-tube for the product or products of the reaction, and may be placed in connection with a trough containing either water or mercury. The apparatus is first filled with the gas to be experimented upon, then the fluorine is allowed to enter, and an observation of what occurs may be made through the fluor-spar windows. One most important precaution to take in collecting the gaseous products over mercury is not to permit the platinum delivery-tube to dip more than two or at most three millimetres under the mercury, as otherwise the levels of the liquid in the two limbs of the electrolysis U-tube become so different owing to the pressure, that the fluorine from one side mixes with the hydrogen evolved upon the other, and there is a violent explosion.

ACTION OF FLUORINE UPON THE NON-METALLIC ELEMENTS.

Hydrogen.—As just described, hydrogen combines with fluorine, even at − 23° and in the dark, with explosive force. This is the only case in which two elementary gases unite directly without the intervention of extraneous energy. If the end of the tube delivering fluorine is placed in an atmosphere of hydrogen, a very hot blue flame, bordered with red, at once appears at the mouth of the tube, and vapour of hydrofluoric acid is produced.

Oxygen.—Fluorine has not been found capable of uniting with oxygen up to a temperature of 500°. On ozone, however, it appears to exert some action, as will be evident from the following experiment. It was shown in 1887 that fluorine decomposes water, forming hydrofluoric acid, and liberating oxygen in the form of ozone. When a few drops of water are placed in the apparatus shown in Fig. 3, and fluorine allowed to enter, the water is instantly decomposed, and on looking through the fluor-spar ends a thick dark cloud is seen over the spot where each drop of water had previously been. This cloud soon diminishes in intensity, and is eventually replaced by a beautiful blue gas—ozone in a state of considerable density. If the product is chased out by a stream of nitrogen as soon as the dense cloud is formed, a very strong odour is perceived, different from that of either fluorine or ozone, but which soon gives place to the unmistakable odour of ozone. It appears as if there is at first produced an unstable oxide of fluorine, which rapidly decomposes into fluorine and ozone.

Nitrogen and *chlorine* appear not to react with fluorine.

Sulphur.—In contact with fluorine gas, sulphur rapidly melts and inflames. A gaseous fluoride of sulphur is formed, which possesses a most penetrating odour, somewhat resembling that of chloride of sulphur. The gas is incombustible, even in oxygen. When warmed in a glass vessel, the latter becomes etched, owing to the formation of silicon tetrafluoride, SiF_4. Selenium and tellurium behave similarly, but form crystalline solid fluorides.

Bromine vapour combines with fluorine in the cold with production of a very bright but low-temperature flame. If the fluorine is evolved in the midst of pure dry liquid bromine, the combination is immediate, and occurs without flame.

Iodine.—When fluorine is passed over a fragment of iodine contained in the horizontal tube, combination occurs, with production of a pale flame. A very heavy liquid, colourless when free from dissolved iodine, and fuming strongly in the air, condenses in the cooled receiver. This liquid fluoride of iodine attacks glass with great energy, and decomposes water when dropped into that liquid with a noise like that produced by red-hot iron. Its properties agree with those of the fluoride of iodine prepared by Gore by the action of iodine on silver fluoride.

Phosphorus.—Immediately phosphorus, either the ordinary yellow variety or red phosphorus, comes in contact with fluorine, a most lively action occurs, accompanied by vivid incandescence. If the fluorine is in excess, a fuming gas is evolved, which gives up its excess of fluorine on collecting over mercury, and is soluble in water. This gas is phosphorus pentafluoride, PF_5, prepared some years ago by Prof. Thorpe. If, on the contrary, the phosphorus is in excess, a gaseous mixture of this pentafluoride with a new fluoride, the trifluoride, PF_3, a gas insoluble in water, but which may be absorbed by caustic potash, is obtained. The trifluoride, in turn, combines with more fluorine to form the pentafluoride, the reaction being accompanied by the appearance of a flame of comparatively low temperature.

Arsenic combines with fluorine at the ordinary temperature with incandescence. If the current of fluorine is fairly rapid, a colourless fuming liquid condenses in the receiver, which is mainly arsenic trifluoride, AsF_3, but which appears also to contain a new fluoride, the pentafluoride, AsF_5, inasmuch as the solution in water yields the reactions of both arsenious and arsenic acids.

Carbon —Chlorine does not unite with carbon even at the high temperature of the electric arc, but fluorine reacts even at the ordinary temperature with finely-divided carbon. Purified lampblack inflames instantly with great brilliancy, as do also the lighter varieties of wood charcoal. A curious phenomenon is noticed with wood charcoal: it appears at first to absorb and condense the fluorine, then quite suddenly it bursts into flame with bright scintillations. The denser varities of charcoal require warming to 50° or 60° before they inflame, but if once the combustion is started at any point it rapidly propagates itself throughout the entire piece. Graphite must be heated to just below dull redness in order to effect combination; while the diamond has not yet been attacked by fluorine, even at the temperature of the Bunsen flame. A mixture of gaseous fluorides of carbon are produced whenever carbon of any variety is acted upon by fluorine, the predominating constituent being the tetrafluoride, CF_4.

Boron.—The amorphous variety of boron inflames instantly in fluorine, with projection of brilliant sparks and liberation of dense fumes of boron trifluoride, BF_3. The adamantine modification behaves similarly if powdered. When the experiment is performed in the fluor-spar tube, the gaseous fluoride may be collected over mercury. The gas fumes strongly in the air, and is instantly decomposed by water.

Silicon.—The reaction between fluorine and silicon is one of the most beautiful of all these extraordinary manifestations of chemical activity. The cold crystals become immediately white-hot, and the silicon burns with a very hot flame, scattering showers of star-like, white-hot particles in all directions. If the action is stopped before all the silicon is consumed, the residue is found to be fused. As crystalline silicon only melts at a temperature superior to 1200°, the heat evolved must be very great. If the reaction is performed in the fluor-spar tube, the resulting gaseous silicon tetrafluoride, SiF_4, may be collected over mercury.

Amorphous silicon likewise burns with great energy in fluorine.

ACTION OF FLUORINE UPON METALS.

Sodium and *potassium* combine with fluorine with great vigour at ordinary temperatures, becoming incandescent, and forming their respective fluorides, which may be obtained crystallized from water in cubes. Metallic *calcium* also burns in fluorine gas, forming the fused fluoride, and occasionally minute crystals of fluor-spar. *Thallium* is rapidly converted to fluoride at ordinary temperatures, the temperature rising until the metal melts and finally becomes red-hot. Powdered *magnesium* burns with great brilliancy. *Iron*, reduced by hydrogen, combines in the cold with immediate incandescence, and formation of an anhydrous, readily soluble, white fluoride. *Aluminium*, on heating to low redness, gives a very beautiful luminosity, as do also *chromium* and *manganese*. The combustion of slightly warmed zinc in fluorine is particularly pretty as an experiment, the flame being of a most dazzling whiteness. *Antimony* takes fire at the ordinary temperature, and forms a solid white fluoride. *Lead* and *mercury* are attacked in the cold, as previously described, the latter with great rapidity. *Copper* reacts at low redness, but in a strangely feeble manner, and the white fumes formed appear to combine with a further quantity of fluorine to form a perfluoride. The main product is a volatile white fluoride. *Silver* is only slowly attacked in the cold. When heated, however, to 100°, the metal commences to be covered with a yellow coat of anhydrous fluoride, and on heating to low redness combination occurs, with incandescence, and the resulting fluoride becomes fused, and afterwards presents a satin-like aspect. *Gold* becomes converted into a yellow deliquescent volatile fluoride when heated to low redness, and at a slightly higher temperature the fluoride is dissociated into metallic gold and fluorine gas.

The action of fluorine on *platinum* has been studied with special care. It is evident, in view of the corrosion of the positive platinum terminal of the electrolysis apparatus, that nascent fluorine rapidly attacks platinum at a temperature of − 23°. At 100°, however, fluorine gas appears to be without action on platinum. At 500°–600° it is attacked strongly, with formation of the tetrafluoride, PtF_4, and a small quantity of the protofluoride, PtF_2. If the fluorine is admixed with vapour of hydrofluoric acid, the reaction is much more vigorous, as if a fluorhydrate of the tetrafluoride, perhaps $2HF.PtF_4$, were formed. The tetrafluoride is generally found in the form of deep-red fused masses, or small yellow crystals resembling those of anhydrous platinum chloride. The salt is volatile and very hygroscopic. Its behaviour with water is peculiar. With a small quantity of water a brownish-yellow solution is formed, which, however, in a very short time becomes warm and the fluoride decomposes; platinic hydrate is precipitated, and free hydrofluoric acid remains in solution. If the quantity of water is greater, the solution may be preserved for some minutes without decomposition. If the liquid is boiled, it decomposes instantly. At a red heat platinic fluoride decomposes into metallic platinum and fluorine, which is evolved in the free state. This reaction can therefore be employed as a ready means of preparing fluorine, the fluoride only requiring to be heated rapidly to redness in a platinum tube closed at one end, when crystallized silicon held at the open end will be found to immediately take fire in the escaping fluorine. The best mode of obtaining the fluoride of platinum for this purpose is to heat a bundle of platinum wires to low redness in the fluor-spar reaction tube in a rapid stream of fluorine. As soon as sufficient fluoride is formed on the wires, they are transferred to a well-stoppered dry glass tube, until required for the preparation of fluorine.

ACTION OF FLUORINE UPON NON-METALLIC COMPOUNDS.

Sulphuretted hydrogen.—When the horizontal tube shown in Fig. 3 is filled with sulphuretted hydrogen gas and fluorine is allowed to enter, a blue flame is observed on looking through the fluor-spar windows playing around the spot where the fluorine is being admitted. The decomposition continues until the whole of the hydrogen sulphide is converted into gaseous fluorides of hydrogen and sulphur.

Sulphur dioxide is likewise decomposed in the cold, with production of a yellow flame and formation of fluoride of sulphur.

Hydrochloric acid gas is also decomposed at ordinary temperatures with flame, and, if there is not a large excess of hydrochloric acid present, with detonation. Hydrofluoric acid and free chlorine are the products.

Gaseous *hydrobromic* and *hydriodic acids* react with fluorine in a similar manner, with production of flame and formation of hydrofluoric acid. Inasmuch, however, as bromine and iodine combine with fluorine, as previously described, these halogens do not escape, but burn up to their respective fluorides. When fluorine is delivered into an aqueous solution of hydriodic acid, each bubble as it enters produces a flash of flame, and if the fluorine is being evolved fairly rapidly there is a series of very violent detonations. A curious reaction also occurs when fluorine is similarly passed into a 50 per cent. aqueous solution of hydrofluoric acid itself, a flame being produced in the middle of the liquid, accompanied by a series of detonations.

Nitric acid vapour reacts with great violence with fluorine, a loud explosion resulting. If fluorine is passed into the ordinary liquid acid, each bubble as it enters produces a flame in the liquid.

Ammonia gas is decomposed by fluorine with formation of a yellow flame, forming hydrofluoric acid and liberating nitrogen. With a solution of the gas in water, each bubble of fluorine produces an explosion and flame, as in case of hydriodic acid.

Phosphoric anhydride, when heated to low redness, burns with a pale flame in fluorine, forming a gaseous mixture of fluorides and oxyfluoride of phosphorus. *Pentachloride and trichloride of phosphorus* both react most energetically with fluorine, instantly producing a brilliant flame, and evolving a mixture of phosphorus pentafluoride and free chlorine.

Arsenious anhydride also affords a brilliant combustion, forming the liquid trifluoride of arsenic, AsF_3. This liquid in turn appears to react with more fluorine with considerable evolution of heat, probably forming the pentafluoride, AsF_5. *Chloride of arsenic*, $AsCl_3$, is converted with considerable energy to the trifluoride, free chlorine being liberated.

Carbon bisulphide inflames in the cold in contact with fluorine, and if the fluorine is led into the midst of the liquid a similar production of flame occurs under the surface of the liquid, as in case of nitric acid. No carbon is deposited, both the carbon and sulphur being entirely converted into gaseous fluorides.

Carbon tetrachloride, as previously mentioned, reacts only very slowly with fluorine. The liquid may be saturated with gaseous fluorine at 15°, but on boiling this liquid a gaseous mixture is evolved, one constituent of which is carbon tetrafluoride, CF_4, a gas readily capable of absorption by alcoholic potash. The remainder consists of another fluoride of carbon, incapable of absorption by potash, and chlorine. A mixture of the vapours of carbon tetrachloride and fluorine inflames spontaneously with detonation, and chlorine is liberated without deposition of carbon.

Boric anhydride is raised to a most vivid incandescence by fluorine, the experiment being rendered very beautiful by the abundant white fumes of the trifluoride which are liberated.

Silicon dioxide, one of the most inert of substances at the ordinary temperature, takes fire in the cold in contact with fluorine, becoming instantly white-hot, and rapidly disappearing in the form of silicon tetrafluoride. The *chlorides* of both *boron* and *silicon* are decomposed by fluorine, with formation of fluorides and liberation of chlorine, the reaction being accompanied by the production of flame.

ACTION OF FLUORINE UPON METALLIC COMPOUNDS.

Chlorides of the metals are instantly decomposed by fluorine, generally at the ordinary temperature, and in certain cases, antimony trichloride for instance, with the appearance of flame. Chlorine is in each case liberated, and a fluoride of the metal formed. A few require heating, when a similar decomposition occurs, often accompanied by incandescence, as in case of chromium sesquichloride.

Bromides and *iodides* are decomposed with even greater energy, and the liberated bromine and iodine burn in the fluorine with formation of their respective fluorides.

Cyanides react in a most beautiful manner with fluorine, the displaced cyanogen burning with a purple flame. Potassium ferrocyanide in particular affords a very pretty experiment, and reacts in the cold. Ordinary potassium cyanide requires slightly warming in order to start the combustion.

Fused *potash* yields potassium fluoride and ozone. Aqueous potash does not form potassium hypofluorite when fluorine is bubbled into it, but only potassium fluoride. *Lime* becomes most brilliantly incandescent, owing partly to the excess being raised to a very high temperature by the heat developed during the decomposition, and partly to the phosphorescence of the calcium fluoride formed.

Sulphides of the alkalies and alkaline earths are also immediately rendered incandescent, fluorides of the metal and sulphur being respectively formed.

Boron nitride behaves in an exceedingly beautiful manner, being attacked in the cold, and emitting a brilliant blue light which is surrounded by a halo of the fumes of boron fluoride.

Sulphates, *nitrates*, and *phosphates* generally require the application of more or less heat, when they too are rapidly and energetically decomposed. Calcium phosphate is attacked in the cold like lime, giving out a brilliant white light, and producing calcium fluoride and gaseous oxyfluoride of phosphorus, POF_3. *Calcium carbonate* also becomes raised to brilliant incandescence when exposed to fluorine gas, as does also normal *sodium carbonate;* but curiously enough the bicarbonates of the alkalies do not react with fluorine even at red heat. Perhaps this may be explained by the fact that fluorine has no action at available temperatures upon carbon dioxide.

ACTION OF FLUORINE UPON A FEW ORGANIC COMPOUNDS.

Chloroform.—When chloroform is saturated with fluorine, and subsequently boiled carbon tetrafluoride, hydrofluoric acid and chlorine are evolved. If a drop of chloroform is agitated in a glass tube with excess of fluorine, a violent explosion suddenly occurs, accompanied by a flash of flame, and the tube is shattered to pieces. The reaction is very lively when fluorine is evolved in the midst of a quantity of chloroform, a persistent flame burns beneath the surface of the liquid, carbon is deposited, and fluorides of hydrogen and carbon are evolved together with chlorine.

Methyl chloride is decomposed by fluorine, even at −23°, with production of a yellow flame, deposition of carbon, and liberation of fluorides of hydrogen and carbon and free chlorine. With the vapour of methyl chloride, as pointed out in the description of the electrolysis, violent explosions occur.

Ethyl alcohol vapour at once takes fire in fluorine gas, and the liquid is decomposed with explosive violence without deposition of carbon. Aldehyde is formed to a considerable extent during the reaction.

Acetic acid and *benzene* are both decomposed with violence, their cold vapours burn in fluorine, and when the latter is bubbled through the liquids themselves, flashes of flame, and often most dangerous explosions, occur. In the case of benzene, carbon is deposited, and with both liquids fluorides of hydrogen and carbon are evolved. *Aniline* likewise takes fire in fluorine, and deposits a large quantity of carbon, which, however, if the fluorine is in excess, burns away completely to carbon tetrafluoride.

Such are the main outlines of these later researches of M. Moissan, and they cannot fail to impress those who read them with the prodigious nature of the forces associated with those minutest of entities, the chemical atoms, as exhibited at their maximum, in so far as our knowledge at present goes, in the case of the element fluorine.

A. E. Tutton.

THE HUXLEY LABORATORY FOR BIOLOGICAL RESEARCH, AND THE MARSHALL SCHOLARSHIP.

SCIENTIFIC friends and former pupils of Prof. Huxley will alike be gratified to learn that an appropriate method has been devised for establishing a permanent memorial of his great services to the institution with which his name has been so long identified. The late Sir Warington Smyth, whose loss we had to deplore rather more than a year ago, was the last surviving member of the original staff of the School of Mines, as founded by Sir Henry de la Beche in 1851. Prof. Huxley, who, as long ago as 1854, succeeded Edward Forbes in the Chair of Natural History, continues to hold the post of Honorary Dean of the Royal College of Science, with which the School of Mines is now incorporated; and although, since 1885, compelled by ill-health to discontinue the work of lecturing, he is still, we are happy to say, able to take a kindly interest in, and to exercise a general supervision over, the biological studies carried on in the school.

How much the Central Institution for training teachers in science, which is now located at South Kensington, owes to the organizing faculty and unremitting labours of Prof. Huxley, only those who have been associated with him in the work can form any just estimate. During the first twenty years of its existence all attempts at practical teaching in the School of Mines were restricted to the subjects of chemistry and metallurgy, the space available in the Jermyn Street buildings only permitting of the existence of very small and inconvenient laboratories in connection with those two branches of science.

Soon after the first establishment of the school, larger and more convenient premises for carrying on the chemical instruction had to be obtained in Oxford Street; and in 1872, on the unanimous recommendation of the Council, the teaching of chemistry, physics, and biology, was transferred to the building at South Kensington, which had been originally designed as a School of Naval Architecture. At subsequent dates, as the inadequacy of the Jermyn Street buildings to accommodate both the school and the Geological Survey made itself more strongly felt, the divisions of geology, mineralogy, metallurgy, applied mechanics, and mining, were successively removed to the same place.

No sooner did Prof. Huxley find an opportunity afforded to him, than he energetically devoted himself to the realization of a long-cherished scheme for establishing a system of practical laboratory-instruction in biology, including both its zoological and its botanical aspects. The ground was broken by a short vacation course, in which an attempt was made to supply such practical instruction to persons engaged in teaching; this course was given in the summer of 1871, and in the following year the same system of laboratory-instruction in biology was introduced into the ordinary School of Mines curriculum. In establishing at South Kensington the biological laboratory which has become the model of so many similar institutions at home and abroad, Prof. Huxley sought and obtained the advice and co-operation of many of his fellow-workers in science, among whom may be specially mentioned Profs. Michael Foster, Thiselton Dyer, Ray Lankester, and Rutherford, with Dr. Martin and Dr. Vines. In carrying on and further developing the work, he has had the assistance of Profs. Jeffrey Parker and F. O. Bower, in the zoological and botanical departments respectively, and, in succession to them, of Mr. G. B. Howes and Dr. D. H. Scott.

From the period of the first foundation of the School of Mines, the importance had been kept in mind of combining original research with the work of teaching. No one at the present day needs to be reminded of the numerous important investigations which have been prosecuted by Prof. Huxley, both at Jermyn Street and South Kensington. Memoirs of the highest value on various branches of comparative anatomy and palæontology have been interspersed with notable contributions to geology, to anthropology, and to botany; and from time to time excursions have been made still farther afield (predatory excursions they were regarded by some), into realms of thought more remote from the ordinary domain of the zoologist. But in all these varied avocations the interests of the teaching work were never forgotten; and it was made evident that the teacher, while carrying on investigations himself, was ever ready to suggest, stimulate, and supervise the investigations of others.

When, in 1885, ill-health compelled Prof. Huxley to relinquish his daily occupations in the school, it was found that, during the more than thirty years' occupancy of his post, he had accumulated a most valuable library of research, composed of treatises and journals dealing with every branch of biological science. This library he generously determined to present to the institution, the interests of which he had so long and earnestly laboured to promote. The Council of the School, in accepting this valuable gift, recommended that the room where these books were kept, and in which Prof. Huxley had so long carried on his work, should be entirely set apart for biological research; and the proposal at once met with the sanction of the Lords of the Committee of Council on Education.

The Huxley Laboratory for Biological Research is now arranged to accommodate two students, who will undertake investigations in connection with some branch of zoology, botany, or palæontology, the work being carried on under the supervision of the professors and assistant professors of the school. With a valuable library and all necessary appliances for work supplied to them, it may be hoped that the *genius loci* will not be without its influence upon these research students, and that a long series of important observations may be made, which will constitute an enduring and a worthy memorial of Prof. Huxley's connexion with the school.

It happens, very opportunely, that something in the way of a small endowment has already been provided to aid this scheme of biological research. As long ago as 1882, Miss Sarah Marshall, of Warwick Gardens, Kensington, wrote to Prof. Huxley, informing him of her intention to bequeath the sum of £1000, and her scientific books and instruments, to the Department of Science and Art, with a view to the establishment of a prize or scholarship in biology, in memory of her father, the late Mr. Marshall of the Bank of England. By the recent death of Miss Marshall, this bequest has now passed into the hands of the Lords of the Committee of Council on Education, and, by the advice of the Council of the Royal College of Science, it has been decided that the interest of the legacy shall be annually paid as a scholarship to a meritorious student, to aid him in carrying on some biological investigation in the Huxley Laboratory. We can only hope that this modest attempt at the endowment of research may be attended with success; and that this success may be so conspicuous as to encourage others to imitate the example of Miss Marshall, so that bequests of a similar character may be made in connexion with this and other institutions where scientific researches can be carried on.

ON VAN DER WAALS'S TREATMENT OF LAPLACE'S PRESSURE IN THE VIRIAL EQUATION: IN ANSWER TO LORD RAYLEIGH.

MY DEAR LORD RAYLEIGH,—From the heading of your first letter, and from the wide scope of the passage you quoted from my paper, I imagined that you intended to raise the whole question of Van der Waals's treatment of Laplace's pressure. Otherwise I should not, in my answer, have referred to his b or to the unfortunate results of comparing his formula with experiment. I should, in fact, have contented myself with the acknowledgment that you had given an accurate account of the contents of a portion of Van der Waals's earlier chapters, which I had carelessly missed on the first hasty perusal; and that these contents justified the expression $3Kv/2$ as the virial of Laplace's pressure. But to this I should certainly have added that, even had I been fully cognizant of that portion of the pamphlet when I wrote my paper, I should probably not have modified (at least to any serious extent) the passage you quoted.

For (1) that passage contains the distinct statement that, from the statical point of view, reasons "satisfactory on the whole" were given by Van der Waals for regarding Laplace's pressure as proportional to the square of the density. And it would have been illogical on my part to object, except on the ground of insufficient generality, to the equation

$$\left(p + \frac{a}{v^2}\right)v = \tfrac{1}{3}\Sigma(mu^2),$$

though I might have regarded the mode of its establishment as obscure or even doubtful.

In fact, the equation which is one of the main features of my own paper, viz. :—

$$pv + \frac{A}{v+a} = \tfrac{1}{3}\Sigma(mu^2) \,.\, \left(1 + \frac{e}{v+a}\right),$$

includes it as the particular case when

$$e = 0, \quad a = 0.$$

What I objected to was a totally different thing :—viz. the above equation manipulated by the introduction of the factor $(v - b)/v$ in the left-hand member.

Again (2) the equation

$$p(v - \beta) = \tfrac{1}{3}\Sigma(mu^2)$$

is obtained in my paper (§ 64), and is there spoken of as "perfectly *legitimate*," but *only* on the distinct condition that

$$\beta\Sigma(mu^2)/3v,$$

where β is four times the sum of the volumes of the particles (§ 30), "*be small in comparison with the other terms in the* [virial] *equation.*" As one of these terms is the quantity $\Sigma(mu^2)/3$ itself, this implies that for the truth of the equation β/v must be a small fraction; and it is most certainly not so at the critical point of carbonic acid, which furnished the first and one of the most important cases for the application of the virial method. In fact the equation above, when correctly obtained, comes originally in the form (in which it ought to be preserved)

$$pv = \tfrac{1}{3}\Sigma(mu^2) \,.\, \left(1 + \frac{\beta}{v}\right);$$

again a particular case of my own equation, viz. when

$$A = 0, \quad a = 0, \quad e = \beta.$$

Here the factor $1/v$ is (roughly) proportional to the number of collisions per particle per second, and it is in that capacity that it appears in the equation. As I said in my former letter, it is impossible (at least with Van der Waals's mode of interpreting $\Sigma(mu^2)$) to derive from this a cubic in v; even when the term a/v^2 is introduced as a simple addition to p :—unless, for the express purpose of obtaining the indispensable cubic, we write $v/(v - \beta)$ in place of $(v + \beta)/v$, on the right-hand side; which is, practically, what Van der Waals does. The true mode of getting a cubic here, if we keep to Van der Waals's interpretation of $\Sigma(mu^2)$, is to write $\beta/(v - \gamma)$ instead of β/v. This can, to a certain extent at least, be justified; the other method can not.

On the question of the introduction by Van der Waals of the factor $(v - b)/v$, whether or not it is applied alike to p and to K, I regret to find that our views must continue to differ. For it appears to me that when once the various terms of the virial equation have been correctly extracted from the expression $\Sigma(Rr)$, we have no right to modify any of them. There seems therefore to be no doubt whatever that the procedure in Van der Waals's sixth chapter is entirely wrong in principle :—except in so far as (in the German version) he borrows some correct expressions from Lorentz. The meanings of v and of p, in the term pv of the virial equation, are (from the very beginning of the inquiry) definitely assigned as total volume and external pressure :—so that this term cannot in any way be altered. No more can the term $\Sigma(mu^2)/3$, or the ratio of these two terms. Van der Waals's argument seems (for his pamphlet is everywhere somewhat obscure) to be that (when there is no molecular force) *in consequence of the finite diameters of the particles the pressure, for a given amount of kinetic energy, will be greater than if these were mere points.* Perfectly true :—but we must seek the expression for this increase of pressure in the remaining parts of the term $\Sigma(Rr)$, and *not* artificially introduce it by diminishing the multiplier of p in a term already definitely extracted. And further, if this procedure of Van der Waals were allowed to pass without protest in so far as the term pv is concerned, I think that we should logically be forced to treat the term Kv (not to the same but) to a very different factor :—for *here* the consideration of the finite volumes of the particles would appear to call for a *reduced* rather than an increased value of K; and therefore analogy would require a multiplication of the term Kv by some such expression as $(v + \gamma)/v$, where γ is essentially *positive.*—Yours very truly,

P. G. Tait.

Edinburgh, 17/10/91.

NOTES.

To-day the Senate of Cambridge University will decide whether official inquiry shall be made as to the expediency of allowing alternatives for one of the two classical languages in the Previous Examination, either to all students or to any classes of students other than those already exempted. Everyone who devotes attention to questions connected with the higher education recognizes the importance of the issue, and the discussion of the subject has been followed with wide-spread interest.

The ordinary general meeting of the Institution of Mechanical Engineers began yesterday evening, and will be continued this evening, at 25 Great George Street, Westminster. The papers to be read and discussed, as we have already stated, are by Mr. Samuel Boswell and Prof. W. C. Roberts-Austen, F.R.S.

The Geologists' Association will hold a *conversazione* at University College, Gower Street, on Friday evening, November 6. Members are invited to send exhibits, and to let the secretary know the nature of the object or objects they propose to show.

At the meeting of the Royal Horticultural Society in the Drill Hall, Westminster, on Tuesday, there was an interesting display of autumn foliage arranged for æsthetic effect. A lecture was delivered by Mr. H. J. Veitch, who urged that trees and shrubs in gardens and plantations should be selected, not only with a view to their summer beauty, but also with regard to their autumn hues; and he had many suggestions to offer as to the various ways in which these hues may be most effectively contrasted.

Prof. Boys has arranged his apparatus for the repetition of the Cavendish experiment in the basement of the Clarendon Laboratory, Oxford. The experiment will be proceeded with immediately.

We regret to have to record the death of Dr. Philip Herbert Carpenter, F.R.S., the fourth son of the late Dr. W. B. Carpenter, C.B., F.R.S. He was found dead in his dressing-room at Eton College, on Wednesday, October 21. At the inquest it was found that he had killed himself by the administration of chloroform during temporary insanity. Dr. Carpenter was in his fortieth year, and had been a science master in Eton since 1877. The following summary of his scientific work in given by the *Times*. He was a member of the scientific staff of the deep-sea exploring expeditions of Her Majesty's steamships *Lightning* (1868) and *Porcupine* (1869-70); and in 1875 he was appointed assistant naturalist to Her Majesty's ship *Valorous*, which accompanied Sir G. Nares's Arctic expedition to Disco Island, and spent the summer sounding and dredging in Davis Strait and the North Atlantic. Dr. Carpenter devoted himself continuously from 1875 to studying the morphology of the Echinoderms, more particularly of the Crinoids, both recent and fossil. In 1883 he was awarded the Lyell Fund by the Geological Society of London in recognition of the value of his work, and in 1885 was elected a Fellow of the Royal Society. His chief memoirs and papers were as follows:—"Notes on Echinoderm Morphology," i.-xi., 1878-87; "On the Genus Actinometra," 1877; "Report upon the Crinoidea dredged by H.M.S. *Challenger*," Part I. "The Stalked Crinoids," 1885, Part II. "The Comatulæ," 1888; "Report upon the Comatulæ dredged by the U.S. Coast Survey in the Caribbean Sea," 1890. In conjunction with Mr. R. Etheridge, Jun., he prepared the "Catalogue of the Blastoidea in the Geological Department of the British Museum," 1886; and he also wrote numerous papers published in the Proceedings or Transactions of the Royal, Linnean, and Geological Societies.

Mr. George Sibley, who was for many years well known as an engineer in India, and had also a considerable reputation as a traveller, died at his residence at Catherham on Sunday last at the age of ixty-seven. It is understood that Mr. Sibley has left a legacy for the purpose of founding engineering scholarships in the University of Calcutta.

Dr. J. Eduard Polak, who died at Vienna on October 8, at the age of seventy-one, was one of the most eminent Persian cholars of his time. He went in 1851 to Teheran, where he lectured at the medical school, and became physician to the Shah. During his nine years' residence in Persia he visited most parts of the country; and on his return to Vienna he wrote his well-known work, "Persien: das Land und seine Bewohner," in which he presented an excellent summary of the knowledge he had acquired. In response to an invitation from the Shah, he again visited Teheran. He read before the Geographical and Anthropological Societies of Vienna many valuable papers on Persia and its antiquities.

The International Geological excursion in America, which started on September 2 last, ended on October 9 after a most successful and interesting trip. In all there were ninety geologists, and the arrangements as regards trains, &c., left nothing to be desired. The route chosen lay through the petroleum districts of Pennsylvania, the prairies of Wisconsin, Minnesota, and Dakotah, the corn-lands of North America, and the twin centres St. Paul and Minneapolis. From the Yellowstone River the party journeyed to the beautiful geyser region of the National Park, where they made a stay of seven days, then to the rising mountain district of Butte, as well as to the Mormon town situated in the middle of the salt wastes of the Great Salt Lake. They then skirted the table-lands in South Utah, and turned towards the Rocky Mountains, where they visited the chief places of geological interest, including Pike's Peak, the Garden of the Gods, &c. At this point many of the party returned home, going by way of Chicago, Niagara Falls, and New York. The smaller number that remained undertook a laborious and exhausting expedition through the deserts of New Mexico and Arizona to the San Francisco mountains and to the Grand Cañon of Colorado; they visited a group of 165 volcanoes and craters, and also a deep valley the sides of which, with their many and various-coloured stones, fall 5800 to 6000 feet to the great Colorado River below. From this standpoint they had an excellent view of the materials composing the upper surfaces of the earth's crust, and they could not but be struck by the magnitude and grandeur of the work accomplished by Nature in digging out this enormous river cañon. The following are some of the places visited on the return journey: La Junta, Kansas City, Chicago, Niagara Falls, Albany, and Boston. Altogether the excursion was a thorough success, and the Americans deserve much credit for having arranged so good a programme for their visitors.

Prof. Russell and his party have returned from the Alaskan wilds, which they penetrated to a distance of forty miles inland, from Icy Bay to the base of Mount St. Elias. They constructed a camp, and remained there two months, making geological surveys and taking observations. Prof. Russell says:—"We began the ascent of Mount St. Elias on June 3. Our progress was not obstructed until we reached an altitude of nearly 10,000 feet. Then we found glaciers. After many perilous adventures we attained the height of 14,500 feet. This has been the estimated height of the mountain, but we found it nearly 5000 feet higher. It was impossible for us to proceed any further, as we were suffering too much from the hardships already endured. Many of the men were exhausted and very weak. The Alaskan Indians were most hospitable to us."

The report by Mr. James Dredge and Sir Henry Trueman Wood on their recent visit to Chicago is printed in the Journal of the Society of Arts (October 23). This report was presented last week to the Royal Commission which has been appointed to organize the English Section at the Chicago "World's Fair." The Commission have decided to appoint the following Committees: Finance, Fine Arts, Indian, Colonial, Engineering, General Manufactures, Electricity, Agriculture, Mines and Metallurgy, Textile Industries, Science and Education, Transportation; also a Committee of Ladies to correspond with the Ladies' Committee at Chicago. They propose to invite the assistance of Chambers of Commerce as Local Committees. A prospectus relating to the Chicago Exhibition has been issued by the Royal Commission

The Council of the Institution of Civil Engineers have issued for general circulation their regulations as to the admission of students. This is followed by an excellent account of the various educational institutions in the British dominions where instruction is given bearing on the profession of civil engineers.

In his report on the working of the Central Museum, Madras, during 1890-91, Mr. Edgar Thurston, the Superintendent, notes that he made two official tours in company with his taxidermists. During the first of these, as in several previous years, he stayed on Rámesvaram Island, where he was mainly engaged in the collection and preservation of marine worms and molluscan shells, which have since been sent to England and Germany to be worked up. Many specimens of the brightly coloured "coral-fishes," which abound over the fringing coral-reefs, were also preserved by the glycerine process introduced by Mr. A. Haly, of the Colombo Museum, for the preservation of colours. His stay on Rámesvaram Island completed, he paid a short visit to Tuticorin, to work out some doubtful points in connection with the anatomy of the pearl oyster. In his second tour he made large collections illustrative of the arts, industries, manufactures, and natural history of the places visited in the Bangalore, Hassan, Shimoga, and Mysore districts. These collections include Srávanbelgola brass-ware, Soráb and Sagar sandal-wood carving, Channapatna silk and toys, Mysore inlaid ware, gold jewellery from Bélur, butterflies, lizards, snakes, &c. A report on this tour will be published after a further visit to the Mysore province, a large area of which remains to be explored.

The other day, Mr. Flinders Petrie delivered at the Owens College, Manchester, a most interesting address on exploration in Egypt. It had been thought, he said, that the immense mounds of rubbish indicating the sites of towns had been made on purpose, but they resulted from the natural decay of the mud-brick buildings. These heaps of ruined walls and earth and potsherds rose even to eighty feet high in some places; but other ancient sites were much less imposing, and might even not attract notice on the open desert. The higher the mound the longer the place had been inhabited; and if the surface was of a late period, the earlier parts, which were most needed, were under such a depth of rubbish as to be practically inaccessible. Much could be known at first sight; and prospecting had now become as scientific a matter in antiquities as in geology. Knowing, by a glance at the sherds on the top, what was the latest period of occupation of the site, and knowing the usual rate of accumulation of a mud-brick town—about five feet in a century—we could guess how far back the bottom of the mound must be dated. Other remains had different indications. If in the midst of a great mound there was a wide flat crater, that was probably the temple site, surrounded by houses which had accumulated high on all sides of it. Speaking of the results of exploration, Mr. Petrie said that we now realized what the course of the arts had been in Egypt. In the earliest days yet known to us—about 4000 B.C.—we found great skill in executing accurate and massive stonework, such skill as had hardly ever been exceeded. We found elaborate tools used, jewelled saws and tubular drills. We saw the pictorial arts as fully developed as they were for thousands of years later. But what led up to this we were still feeling for.

To what uses did primitive men apply the stone hammers which they made in such large numbers? This question Mr. J. D. McGuire tries to answer in a paper in the *American Anthropologist* for October. His theory is that the hammer was probably "the tool upon which races living in the Stone Age relied more than upon any other object to fashion stone implements." It was used, he thinks, not only to peck an axe or celt into shape, but to rub or polish the implement after it had been shaped; and, to illustrate this, he gives a figure representing a typical hammer of quartzite, from McMinn County, Tennessee, the periphery of which is pitted by use, while the flattened sides show that it must have been a rubbing-stone as well. To prove that the work suggested could be done by a stone hammer, he represents an axe of close-grained black porphyry, which he himself pecked out and grooved by means of such an implement. The task occupied him about five hours. As ordinary stone axes are made of softer material, he thinks they were probably produced in a much shorter time.

Dr. H. von Wlislocki contributes to the current number of *Globus* a capital paper on the handicrafts of Hungarian gypsies, whom he has had many opportunities of observing. If we may judge from the illustrations, they have a considerable aptitude for design. In the summer they make bottles out of pumpkins, which they decorate with various drawings. On each bottle the space is divided into four zones, crosses being cut into the uppermost zone, serpents into the second one, circles into the third, and zigzag lines into the fourth. The crosses mean "May you be happy!"; the serpents, "May you have no enemies!"; the circles, "May you always have money!"; the zigzag lines, "May you be healthy!" Brandy is kept in the bottles; and when a guest is received, the first gypsy who drinks says, "May you be happy!"; the second, "May you have no enemies!"—and so on. Pretty walking-sticks are also among the things made by the Hungarian gypsies. On the top of one of those sketched in the article two female heads are admirably carved. These represent Ana, the Queen of the Keschalyis, or forest fairies, who dwell among the mountains, where they sit—three being always together—on rocks, spreading out their long hair over the valleys, thus giving rise to mists. Queen Ana lives in a black palace, and sometimes wanders over the world in the form of a frog. Frogs, toads, and serpents are her favourite animals. When she meets anyone in her natural form, she exclaims "Ana!", which means "Bring!" Should the person understand the cry and bring a frog, a toad, or a serpent, he is richly rewarded. If he fails to do so, he is either killed with a piece of a rock, or struck by some terrible malady.

The *Times* of October 22 has an interesting article on "Our Position with regard to Rainfall," compiled from the statistics published by Mr. Symons and the Meteorological Office. The rainfall during the present month has been so heavy that in many places the amount up to the morning of the 18th was in excess of the average for the whole month. In London this excess amounted only to 0·3 inch, while at Valentia Island and at Stornoway it amounted to nearly 2 and 3 inches respectively, and the amount which fell during the next few days has greatly increased the excess. But for the 10 years ending with 1889 the rainfall over the United Kingdom differed only by 1 per cent. from the average of the last 50 years. The values for the present year, up to the 18th instant (as shown by the last Weekly Weather Report then published), were rather in excess of the average over the southern, midland, and western parts of England, and the north of Scotland, while in the remaining districts there was still a deficiency. For the whole period since the end of 1889, there was only one district, viz. Scotland (N.), in which the total fall was in excess of the average. In Scotland and the midland and south-western counties of England, the deficiency was still very large. The question is asked—Are we likely to have in the years immediately advancing more or less rain than during the last few years? While the question cannot be answered with absolute confidence, the grouping of years into decades or other regular periods eliminates most of the non-periodic variations, and shows whether any secular alterations are taking place. There is no doubt that since 1887, at all events, the rainfall over England has been much below the average; and a consideration of all the facts leads to the conclusion that such a period of scarcity is very likely to be followed by one of abundance, and that the coming few years will probably be more rainy than those recently experienced, although possibly the increase will not occur in the summer months—at a time when it would be most noticed.

The new number of *Petermann's Mitteilungen* opens with some interesting extracts from the diary of the late Dr. Anton Stecker, written during his journey in Abyssinia and the Galla countries in 1880–83. Stecker died before he had an opportunity of writing a full and systematic account of his travels. In the present extracts he notes not only the physical characteristics of the regions to which they relate, but the manners and customs of the natives. A good map makes it easy for the reader to trace his route.

A Greek gardener lately expressed the opinion that oranges, figs, olives, and grapes grown in Australia are inferior to those grown at Smyrna and Athens. This having been brought to the attention of the Department of Agriculture, New South Wales, letters were addressed to the British Consuls at Naples and Marseilles asking for a consignment of the best varieties of grapes, figs, and olives grown in Italy and France. On receipt of these cuttings, experiments are to be carried out at the most suitable of the experimental stations about to be established throughout the colony, with a view to the propagation of the finest varieties of the respective fruits. With the same object in view application has been made to Mr. T. Hardy, of South Australia, for a number of cuttings of various vines he has cultivated, and to Sir Samuel Davenport, of Beaumont, South Australia, for cuttings of the olive and fig trees grown by him. The whole of these cuttings will go to form the standard collections of all the different kinds of fruit which it is intended to establish at each of the experimental stations.

IN the *Revue Agricole*, published in Mauritius, M. A. Daruty de Grandpré gives an account of his attempts to raise sugar-cane from seeds. The seeds were sent from Barbados by the Governor in March 1890. M. de Grandpré planted them with the greatest care, and after five days was fortunate enough to obtain five minute seedlings out of the hundred seeds used. The young plants he raised did not all prove equally vigorous, and he was able to save only one, which, at the time when his report was written, had formed a fine clump of twenty shoots with long ribbon leaves. "I believe," he says, "that we may with reason cherish the most sanguine hopes from the propagation of sugar-cane from seeds—more especially if we try an intelligent system of cross-fertilization of the varieties we possess—rather than by planting cuttings, which maintain without appreciable alteration the respective characteristics of the parent plants. Thus we shall be able to supplement the weak points in our best varieties of sugar-cane by crossing them with others which are remarkable for the qualities it is intended to infuse into them, and we shall moreover obtain, by a process of selection, a cane rich in saccharine matter, which will enable us to compete successfully against the highly improved sugar-beet."

MR. A. W. MORRIS contributes to the current number of the Journal of the Bombay Natural History Society an interesting paper on abnormal horns of the Indian antelope. We have as yet little definite information as to the cause or causes of such abnormalities. Mr. Morris suggests that severe injuries to the skull, inflicted either during battle or through some accident, are the main causes that produce abnormalities, the horn on the injured side being thrown out of its natural course by the concussion or damage sustained.

THE Academy of Natural Sciences of Philadelphia prints in its Proceedings a list of the Echinoderms obtained by Mr. Frederick Stearns, of Detroit, in the Bahama Islands in the years 1887 and 1888. The list has been drawn up by Mr. J. E. Ives. It includes a description of a new species of Amphiura.

A VALUABLE revised list of British Echinoidea, by Mr. William E. Hoyle, has been printed in the Proceedings of the Royal Physical Society, Edinburgh, and is now issued separately. The author gives a brief diagnosis of each species, such as will enable the collector to identify it on the spot.

MESSRS. J. AND A. CHURCHILL have published a second edition of the English translation of Dr. A. Chauveau's "Comparative Anatomy of the Domesticated Animals." Dr. George Fleming is the translator and editor. In preparing the new edition, Dr. Fleming has kept in view the necessities of advancing veterinary education in the English-speaking schools. He has introduced, therefore, a considerable number of "amendments, alterations, and additions."

MESSRS. HENRY SOTHERAN AND CO. propose to issue a work entitled "Game Birds and Shooting Sketches," by J. G. Millais, F.Z.S. The work will illustrate the habits, modes of capture, and stages of plumage of game birds, and the hybrids and varieties which occur among them.

THE University College of North Wales has issued its Calendar for the year 1891–92.

LECTURES on the following subjects will be given at the Royal Victoria Hall on Tuesday evenings during the month of November:—November 3, Mr. F. W. Rudler, "Some Very Ancient Britons"; November 10, Dr. Rideal, "London Fogs"; November 17, Dr. W. D. Halliburton, "Skin and Bones" (second lecture); November 24, Rev. C. E. Brooke, "A Holiday in the Far West."

THE additions to the Zoological Society's Gardens during the past week include a White-fronted Lemur (*Lemur albifrons* ♂) from Madagascar, presented by Mr. J. M. Nicholl; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. A. D. Watson; a Buffon's Skua (*Stercorarius parasiticus*), North European, presented by Mr. Edward Hart, F.Z.S.; two Common Cuckoos (*Cuculus canorus*), British, presented respectively by Mr. H. Lindsay and Miss Ord; a Burbot (*Lota vulgaris*) from the Trent, presented by Mr. F. T. Burrows; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, a Lion Marmoset (*Midas rosalia*) from South-East Brazil, an Australian Cassowary (*Casuarius australis*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

THE ZODIACAL LIGHT AND AURORÆ.—On the supposition that the zodiacal light is an extension of the solar corona, and that the latter mainly consists of light reflected from meteoritic particles circling round the sun over the spot zones and parallel to the plane of the equator, Mr. M. A. Veeder explains (Rochester Academy of Sciences, January 26, 1891) why in middle latitudes the phenomenon is brightest in March and October, in the former case after sunset, and in the latter before sunrise, and also the fact that at these times one margin of the band is better defined than the other, and more exactly included within the plane of the ecliptic, whilst at other seasons there is decreasing brightness, and both edges become ill-defined.

An investigation of observations of auroræ and magnetic perturbations shows that they may be arranged in periods having the same length as that of a synodic rotation of the sun. And it appears that the areas most frequented by sun-spots are most actively concerned in the production of auroræ. Extending the research, Mr. Veeder believes that the belt-like distribution of atmospheric pressure about the magnetic poles as a centre is very largely dependent upon magnetic induction of solar volcanic origin, conveyed from the sun to the earth through the medium of the coronal extensions referred to above.

COMET *e* 1891.—The following orbit has been computed by Prof. Campbell for the comet discovered by Prof. Barnard on October 2:—

$$T = 1891 \text{ November } 8{\cdot}75 \text{ G.M.T.}$$

$$\left.\begin{aligned} \pi &= 117^\circ\ 44' \\ \text{☊} &= 215\ \ 38 \\ i &= \ \ 75\ \ 50 \end{aligned}\right\} \text{Mean Eq. 1891.}$$

$$q = 1{\cdot}0166.$$

On October 30 the comet is in the position R.A. 10h. 53m. 7s., Decl. − 54° 43′. It is therefore not visible in our latitudes.

TWO NEW ASTEROIDS.—A new minor planet, (319), of the thirteenth magnitude was discovered by M. Charlois on October 8, and another, (320), by Dr. Palisa on October 11.

The latter observer has given the name of Thora to (299), Olga to (304), and Fraternitas to (309).

DOUBLE STARS.—Mr. S. W. Burnham announces that he is preparing a general catalogue of all the double stars discovered by him, and would be glad to receive any unpublished measures of them, Nos. 1 to 1224.

JUPITER'S FIRST SATELLITE.—Some recent observations made at Lick Observatory show that the first satellite of Jupiter is ellipsoidal, and that one of its longer axes is directed to the planet's centre.

THE INTERNATIONAL METEOROLOGICAL CONFERENCE.

THIS meeting, which was more or less of a private character, as it was not organized in any way through diplomatic channels, took place at Munich from August 26 to September 2. It was held in the building of the Technical High School, and was attended by 32 members, representing most European and some extra-European countries. As to the latter, the United States contributed four members, while Brazil and Queensland sent one each. Roumania and Bulgaria for the first time took part in one of these meteorological gatherings. Dr. Lang, the head of the Bavarian meteorological system, was appointed President, and Prof. Mascart (Paris) with Prof. Harrington (Washington) Vice-Presidents. The Secretaries were Dr. Erk (Munich), Mr. Scott, and M. Teisserenc de Bort (Paris).

The following is a brief summary of the most important practical results and recommendations of the Conference.

All temperatures published after 1901 are to be referred to the readings of the air thermometer. Actinometrical observations are not held to be sufficiently certain to justify their general introduction. The application of a ventilating arrangement to wet-bulb thermometers was recommended. *Rain.*—It was decided to count as days of rain those on which 0·005 inch (0·1 mm.) of rain was measured, and to print monthly the number of days on which 0·05 inch (or 1 mm.) fell. *Snow.*—A note is to be made in monthly schedules of the number of days on which about half the country surrounding the station is under snow. *Clouds.*—A new classification of clouds to replace Howard's, proposed by Prof. Hildebrandsson and the Hon. R. Abercromby, was adopted by a large majority, England and the United States being dissentients. A committee was then appointed to consider the question of typical cloud pictures in general, taking the above classification more or less as a basis of arrangement. A report was also received and adopted on the observation of the motions, &c., of cirrus and other high-level clouds. *Wind.*—Robinson's anemometer was the only form of instrument discussed. It was decided that no instrumental results should be published unless the instrument had been previously compared with a standard, either directly or indirectly. *Time.*—A proposal to recommend the adoption of universal or zone time was emphatically rejected, on the ground that local time can alone be used for climatological inquiry. It was further decided in all publications to insist on commencing the day with midnight as 0 hours. *Gravity correction.*—It was decided to introduce the practice of correcting barometrical readings for the force of gravity at lat. 45° after the beginning of the year 1901.

Mr. Wragge, for Queensland, and Captain Pinheiro, for Brazil, gave interesting notices of what is being done for meteorology in their respective countries. It was resolved that an International Meteorological Committee should be constituted to prepare for a possible Congress in Paris in the year 1896. The Committee is to consist of 17 members, of whom 14 were elected, and it was decided to fill the 3 vacancies by the co-option of extra-European meteorologists. The officers of the Committee—Messrs. Wild and Scott—were reappointed.

The questions relating to terrestrial magnetism were referred by the Conference to a special sub-committee, whose decisions will appear in the published report of the proceedings.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 19.—M. Duchartre in the chair.—Memoir on the underground temperatures observed at the Muséum d'Histoire Naturelle, during the winter 1890–91, by M. Henri Becquerel. A thermo-electric arrangement was used for the determination of the temperatures beneath two surfaces, one of which was covered with sand and devoid of vegetation, whilst the other had grass and some plants growing upon it. The two soils were similar, and in each case the temperatures were taken at five points, having depths ranging between 5 cm. and about 60 cm. The observations extend from November 1, 1890, to March 31, 1891, the temperatures being taken at 6 a.m. and 3 p.m. daily. These have been plotted, and the resulting curves strikingly show the variations which occurred in the interval, and the extinction of detail with increased depth. The diurnal variation at the greatest depth was a few tenths of a degree, whilst that of the air was about 14°. At a depth of 18 cm. beneath the sandy covering the variation was the same as in air, but at all the other points the effect was reversed—that is, the temperature fell from 6 a.m. to 3 p.m., and rose during the night. It also appears from the observations that Fourier's theory of the differential relation existing between temperature, time, and depth of thermometer represents very well the propagation of heat in a superficial layer of soil, and that the coefficient of conductivity of this layer for determined conditions of humidity may be deduced from observations of underground temperatures. A certain thickness of earth protects the roots of plants from the effects of a sharp frost, but it may not be equally efficacious against a long one of less intensity, for the velocity of propagation of a variation of temperature, and the depth at which this variation is felt, depends upon the duration of its period. A layer of grass, covering soil, has the same protecting effect during the winter as that of about 50 cm. of mould.—Researches on the cause of rheumatic diathesis, by M. F. P. le Roux.—Observations of Wolf's periodic comet, made at Algiers Observatory with the telescope of 0·50 m. aperture, by MM. Rambaud and Sy. Observations for position were made on August 4, 5, 8, and 31, and on September 7.—On the reduction, to a canonical form, of equations from derived partials of the first order and the second degree, by Mr. Elliot.—On cyclic systems, and on the deformation of surfaces, by M. E. Cosserat.—Calculation of the magnetic rotation of the plane of polarization of light, by M. G. Hinrichs. The simple law connecting the rotation of the plane of polarization with the thickness of the medium traversed is shown to be applicable to the molecular rotation of a normal paraffin.—On a new method for estimating nitric acid and the total nitrogen, by M. E. Boyer. The method is founded upon the reduction of nitric acid to ammonia, by oxalates and sulphur, in the presence of soda-lime.—On the action of nitric acid on dimethyl ortho-anisidine, by M. P. van Romburgh.—On the *globulicide* power of blood serum, by M. G. Daremberg. The author terms "*pouvoir globulicide*" the power possessed by the serum of the blood of one animal to destroy the red corpuscles of the blood of another of a different species. And the destructive power of serum for microbes is called "*pouvoir microbicide.*" The effects produced in each case have been studied.—On the nature of the movement of the chromatophores of Cephalopods, by M. C. Phisalix.
